Before we create an ASP.NET page that uses the computed column created in Step 1, we first need to add the corresponding methods in the BLL. Our ASP.NET page, which we will create in Step 7, will allow users to view and edit suppliers. Therefore, we need our BLL to provide, at minimum, a method to get all of the suppliers and another to update a particular supplier.

Create a new class file named `SuppliersBLLWithSprocs` in the `~/App_Code/BLL` folder and add the following code:

```
using System;
using System.Data;
using System.Configuration;
using System.Web;
using System.Web.Security;
using System.Web.UI;
using System.Web.UI.WebControls;
using System.Web.UI.WebControls.WebParts;
using System.Web.UI.HtmlControls;
using NorthwindWithSprocsTableAdapters;
[System.ComponentModel.DataObject]
public class SuppliersBLLWithSprocs
{
    private SuppliersTableAdapter _suppliersAdapter = null;
    protected SuppliersTableAdapter Adapter
    {
        get
        {
            if (_suppliersAdapter == null)
                _suppliersAdapter = new SuppliersTableAdapter();
            return _suppliersAdapter;
        }
    }
    [System.ComponentModel.DataObjectMethodAttribute
        (System.ComponentModel.DataObjectMethodType.Select, true)]
    public NorthwindWithSprocs.SuppliersDataTable GetSuppliers()
    {
        return Adapter.GetSuppliers();
    }
    [System.ComponentModel.DataObjectMethodAttribute
        (System.ComponentModel.DataObjectMethodType.Update, true)]
    public bool UpdateSupplier(string companyName, string contactName,
        string contactTitle, int supplierID)
    {
        NorthwindWithSprocs.SuppliersDataTable suppliers =
            Adapter.GetSupplierBySupplierID(supplierID);
        if (suppliers.Count == 0)
            // no matching record found, return false
            return false;
        NorthwindWithSprocs.SuppliersRow supplier = suppliers[0];
        supplier.CompanyName = companyName;
        if (contactName == null)
            supplier.SetContactNameNull();
        else
            supplier.ContactName = contactName;
        if (contactTitle == null)
            supplier.SetContactTitleNull();
        else
            supplier.ContactTitle = contactTitle;
        // Update the product record
        int rowsAffected = Adapter.Update(supplier);
        // Return true if precisely one row was updated, otherwise false
        return rowsAffected == 1;
    }
}
```

Like the other BLL classes, `SuppliersBLLWithSprocs` has a `protected` `Adapter` property that returns an instance of the `SuppliersTableAdapter` class along with two `public` methods: `GetSuppliers` and `UpdateSupplier`. The `GetSuppliers` method calls and returns the `SuppliersDataTable` returned by the corresponding `GetSupplier` method in the Data Access Layer. The `UpdateSupplier` method retrieves information about the particular supplier being updated via a call to the DAL s `GetSupplierBySupplierID(supplierID)` method. It then updates the `CategoryName`, `ContactName`, and `ContactTitle` properties and commits these changes to the database by calling the Data Access Layer s `Update` method, passing in the modified `SuppliersRow` object.

> **NOTE**
> Except for `SupplierID` and `CompanyName`, all columns in the Suppliers table allow `NULL` values. Therefore, if the passed-in `contactName` or `contactTitle` parameters are `null` we need to set the corresponding `ContactName` and `ContactTitle` properties to a `NULL` database value using the `SetContactNameNull` and `SetContactTitleNull` methods, respectively.

Step 7: Working with the Computed Column from the Presentation Layer

With the computed column added to the `Suppliers` table and the DAL and BLL updated accordingly, we are ready to build an ASP.NET page that works with the `FullContactName` computed column. Start by opening the `ComputedColumns.aspx` page in the `AdvancedDAL` folder and drag a GridView from the Toolbox onto the Designer. Set the GridView s `ID` property to `Suppliers` and, from its smart tag, bind it to a new ObjectDataSource named `SuppliersDataSource`. Configure the ObjectDataSource to use the `SuppliersBLLWithSprocs` class we added back in Step 6 and click Next.

Figure 11: Configure the ObjectDataSource to Use the `SuppliersBLLWithSprocs` Class (Click to view full-size image)

There are only two methods defined in the `SuppliersBLLWithSprocs` class: `GetSuppliers` and `UpdateSupplier`. Ensure that these two methods are specified in the SELECT and UPDATE tabs, respectively, and click Finish to complete the configuration of the ObjectDataSource.

Upon completion of the Data Source Configuration wizard, Visual Studio will add a BoundField for each of the data fields returned. Remove the `SupplierID` BoundField and change the `HeaderText` properties of the `CompanyName`, `ContactName`, `ContactTitle`, and `FullContactName` BoundFields to Company, Contact Name, Title, and Full Contact Name, respectively. From the smart tag, check the Enable Editing checkbox to turn on the GridView s built-in editing capabilities.

In addition to adding BoundFields to the GridView, completion of the Data Source Wizard also causes Visual Studio to set the ObjectDataSource s `OldValuesParameterFormatString` property to original_{0}. Revert this setting back to its default value, {0} .

After making these edits to the GridView and ObjectDataSource, their declarative markup should look similar to

the following:

```
<asp:GridView ID="Suppliers" runat="server" AutoGenerateColumns="False"
    DataKeyNames="SupplierID" DataSourceID="SuppliersDataSource">
    <Columns>
        <asp:CommandField ShowEditButton="True" />
        <asp:BoundField DataField="CompanyName"
            HeaderText="Company"
            SortExpression="CompanyName" />
        <asp:BoundField DataField="ContactName"
            HeaderText="Contact Name"
            SortExpression="ContactName" />
        <asp:BoundField DataField="ContactTitle"
            HeaderText="Title"
            SortExpression="ContactTitle" />
        <asp:BoundField DataField="FullContactName"
            HeaderText="Full Contact Name"
            SortExpression="FullContactName"
            ReadOnly="True" />
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="SuppliersDataSource" runat="server"
    SelectMethod="GetSuppliers" TypeName="SuppliersBLLWithSprocs"
        UpdateMethod="UpdateSupplier">
    <UpdateParameters>
        <asp:Parameter Name="companyName" Type="String" />
        <asp:Parameter Name="contactName" Type="String" />
        <asp:Parameter Name="contactTitle" Type="String" />
        <asp:Parameter Name="supplierID" Type="Int32" />
    </UpdateParameters>
</asp:ObjectDataSource>
```

Next, visit this page through a browser. As Figure 12 shows, each supplier is listed in a grid that includes the `FullContactName` column, whose value is simply the concatenation of the other three columns formatted as `ContactName` (`ContactTitle` , `CompanyName`) .

Figure 12: Each Supplier is Listed in the Grid (Click to view full-size image)

Clicking the Edit button for a particular supplier causes a postback and has that row rendered in its editing interface (see Figure 13). The first three columns render in their default editing interface - a TextBox control whose `Text` property is set to the value of the data field. The `FullContactName` column, however, remains as text. When the BoundFields were added to the GridView at the completion of the Data Source Configuration wizard, the `FullContactName` BoundField s `ReadOnly` property was set to `true` because the corresponding `FullContactName` column in the `SuppliersDataTable` has its `ReadOnly` property set to `true` . As noted in Step 4, the

`FullContactName` s `ReadOnly` property was set to `true` because the TableAdapter detected that the column was a computed column.

Figure 13: The `FullContactName` Column is Not Editable (Click to view full-size image)

Go ahead and update the value of one or more of the editable columns and click Update. Note how the `FullContactName` s value is automatically updated to reflect the change.

> **NOTE**
>
> The GridView currently uses BoundFields for the editable fields, resulting in the default editing interface. Since the `CompanyName` field is required, it should be converted into a TemplateField that includes a RequiredFieldValidator. I leave this as an exercise for the interested reader. Consult the Adding Validation Controls to the Editing and Inserting Interfaces tutorial for step-by-step instructions on converting a BoundField to a TemplateField and adding validation controls.

Summary

When defining the schema for a table, Microsoft SQL Server allows the inclusion of computed columns. These are columns whose values are calculated from an expression that usually references the values from other columns in the same record. Since the values for computed columns are based on an expression, they are read-only and cannot be assigned a value in an `INSERT` or `UPDATE` statement. This introduces challenges when using a computed column in the main query of a TableAdapter that tries to automatically generate corresponding `INSERT` , `UPDATE` , and `DELETE` statements.

In this tutorial we discussed techniques for circumventing the challenges posed by computed columns. In particular, we used stored procedures in our TableAdapter to overcome the brittleness inherent in TableAdapters that use ad-hoc SQL statements. When having the TableAdapter wizard create new stored procedures, it is important that we have the main query initially omit any computed columns because their presence prevents the data modification stored procedures from being generated. After the TableAdapter has been initially configured, its `SelectCommand` stored procedure can be retooled to include any computed columns.

Happy Programming!

Configuring the Data Access Layer's Connection- and Command-Level Settings (C#)

2/20/2020 • 12 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> The TableAdapters within a Typed DataSet automatically take care of connecting to the database, issuing commands, and populating a DataTable with the results. There are occasions however when we want to take care of these details ourselves, and in this tutorial we learn how to access the database connection- and command-level settings in the TableAdapter.

Introduction

Throughout the tutorial series we have used Typed DataSets to implement the Data Access Layer and business objects of our layered architecture. As discussed in the first tutorial, the Typed DataSet s DataTables serve as repositories of data whereas the TableAdapters act as wrappers to communicate with the database to retrieve and modify the underlying data. The TableAdapters encapsulate the complexity involved in working with the database and saves us from having to write code to connect to the database, issue a command, or populate the results into a DataTable.

There are times, however, when we need to burrow into the depths of the TableAdapter and write code that works directly with the ADO.NET objects. In the Wrapping Database Modifications within a Transaction tutorial, for example, we added methods to the TableAdapter for beginning, committing, and rolling back ADO.NET transactions. These methods used an internal, manually-created `SqlTransaction` object that was assigned to the TableAdapter s `SqlCommand` objects.

In this tutorial we will examine how to access the database connection- and command-level settings in the TableAdapter. In particular, we will add functionality to the `ProductsTableAdapter` that enables access to the underlying connection string and command timeout settings.

Working with Data Using ADO.NET

The Microsoft .NET Framework contains a plethora of classes designed specifically to work with data. These classes, found within the `System.Data` namespace, are referred to as the *ADO.NET* classes. Some of the classes under the ADO.NET umbrella are tied to a particular *data provider*. You can think of a data provider as a communication channel that allows information to flow between the ADO.NET classes and the underlying data store. There are generalized providers, like OleDb and ODBC, as well as providers that are specially designed for a particular database system. For example, while it is possible to connect to a Microsoft SQL Server database using the OleDb provider, the SqlClient provider is much more efficient as it was designed and optimized specifically for SQL Server.

When programmatically accessing data, the following pattern is commonly used:

- Establish a connection to the database.
- Issue a command.
- For `SELECT` queries, work with the resulting records.

There are separate ADO.NET classes for performing each of these steps. To connect to a database using the

SqlClient provider, for example, use the `SqlConnection` class. To issue an `INSERT`, `UPDATE`, `DELETE`, or `SELECT` command to the database, use the `SqlCommand` class.

Except for the Wrapping Database Modifications within a Transaction tutorial, we have not had to write any low-level ADO.NET code ourselves because the TableAdapters auto-generated code includes the functionality needed to connect to the database, issue commands, retrieve data, and populate that data into DataTables. However, there may be times when we need to customize these low-level settings. Over the next few steps we will examine how to tap into the ADO.NET objects used internally by the TableAdapters.

Step 1: Examining with the Connection Property

Each TableAdapter class has a `Connection` property that specifies database connection information. This property s data type and `ConnectionString` value are determined by the selections made in the TableAdapter Configuration wizard. Recall that when we first add a TableAdapter to a Typed DataSet this wizard asks us for the database source (see Figure 1). The drop-down list in this first step includes those databases specified in the configuration file as well as any other databases in the Server Explorer s Data Connections. If the database we want to use does not exist in the drop-down list, a new database connection can be specified by clicking the New Connection button and providing the needed connection information.

Figure 1: The First Step of the TableAdapter Configuration Wizard (Click to view full-size image)

Let s take a moment to inspect the code for the TableAdapter s `Connection` property. As noted in the Creating a Data Access Layer tutorial, we can view the auto-generated TableAdapter code by going to the Class View window, drilling down to the appropriate class, and then double-clicking the member name.

Navigate to the Class View window by going to the View menu and choosing Class View (or by typing Ctrl+Shift+C). From the top half of the Class View window, drill down to the `NorthwindTableAdapters` namespace and select the `ProductsTableAdapter` class. This will display the `ProductsTableAdapter` s members in the bottom half of the Class View, as shown in Figure 2. Double-click the `Connection` property to see its code.

Figure 2: Double-Click the Connection Property in the Class View to View Its Auto-Generated Code

The TableAdapter s `Connection` property and other connection-related code follows:

```
private System.Data.SqlClient.SqlConnection _connection;
private void InitConnection() {
    this._connection = new System.Data.SqlClient.SqlConnection();
    this._connection.ConnectionString =
        ConfigurationManager.ConnectionStrings["NORTHWNDConnectionString"].ConnectionString;
}
internal System.Data.SqlClient.SqlConnection Connection {
    get {
        if ((this._connection == null)) {
            this.InitConnection();
        }
        return this._connection;
    }
    set {
        this._connection = value;
        if ((this.Adapter.InsertCommand != null)) {
            this.Adapter.InsertCommand.Connection = value;
        }
        if ((this.Adapter.DeleteCommand != null)) {
            this.Adapter.DeleteCommand.Connection = value;
        }
        if ((this.Adapter.UpdateCommand != null)) {
            this.Adapter.UpdateCommand.Connection = value;
        }
        for (int i = 0; (i < this.CommandCollection.Length); i = (i + 1)) {
            if ((this.CommandCollection[i] != null)) {
                ((System.Data.SqlClient.SqlCommand)
                    (this.CommandCollection[i])).Connection = value;
            }
        }
    }
}
```

When the TableAdapter class is instantiated, the member variable `_connection` is equal to `null`. When the `Connection` property is accessed, it first checks to see if the `_connection` member variable has been instantiated. If it has not, the `InitConnection` method is invoked, which instantiates `_connection` and sets its `ConnectionString` property to the connection string value specified from the TableAdapter Configuration wizard s first step.

The `Connection` property can also be assigned to a `SqlConnection` object. Doing so associates the new `SqlConnection` object with each of the TableAdapter s `SqlCommand` objects.

Step 2: Exposing Connection-Level Settings

The connection information should remain encapsulated within the TableAdapter and not be accessible to other layers in the application architecture. However, there may be scenarios when the TableAdapter s connection-level information needs to be accessible or customizable for a query, user, or ASP.NET page.

Let s extend the `ProductsTableAdapter` in the `Northwind` DataSet to include a `ConnectionString` property that can be used by the Business Logic Layer to read or change the connection string used by the TableAdapter.

> **NOTE**
>
> A *connection string* is a string that specifies database connection information, such as the provider to use, the location of the database, authentication credentials, and other database-related settings. For a list of connection string patterns used by a variety of data stores and providers, see ConnectionStrings.com.

As discussed in the Creating a Data Access Layer tutorial, the Typed DataSet s auto-generated classes can be extended through the use of partial classes. First, create a new subfolder in the project named `ConnectionAndCommandSettings` underneath the `~/App_Code/DAL` folder.

Figure 3: Add a Subfolder Named `ConnectionAndCommandSettings`

Add a new class file named `ProductsTableAdapter.ConnectionAndCommandSettings.cs` and enter the following code:

```
using System;
using System.Data;
using System.Configuration;
using System.Web;
using System.Web.Security;
using System.Web.UI;
using System.Web.UI.WebControls;
using System.Web.UI.WebControls.WebParts;
using System.Web.UI.HtmlControls;
namespace NorthwindTableAdapters
{
    public partial class ProductsTableAdapter
    {
        public string ConnectionString
        {
            get
            {
                return this.Connection.ConnectionString;
            }
            set
            {
                this.Connection.ConnectionString = value;
            }
        }
    }
}
```

This partial class adds a `public` property named `ConnectionString` to the `ProductsTableAdapter` class that allows any layer to read or update the connection string for the TableAdapter s underlying connection.

With this partial class created (and saved), open the `ProductsBLL` class. Go to one of the existing methods and type in `Adapter` and then hit the period key to bring up IntelliSense. You should see the new `ConnectionString` property available in IntelliSense, meaning that you can programmatically read or adjust this value from the BLL.

Exposing the Entire Connection Object

This partial class exposes just one property of the underlying connection object: `ConnectionString`. If you want to make the entire connection object available beyond the confines of the TableAdapter, you can alternatively change the `Connection` property s protection level. The auto-generated code we examined in Step 1 showed that the

TableAdapter s `Connection` property is marked as `internal`, meaning that it can only be accessed by classes in the same assembly. This can be changed, however, via the TableAdapter s `ConnectionModifier` property.

Open the `Northwind` DataSet, click on the `ProductsTableAdapter` in the Designer, and navigate to the Properties window. There you will see the `ConnectionModifier` set to its default value, `Assembly`. To make the `Connection` property available outside of the Typed DataSet s assembly, change the `ConnectionModifier` property to `Public`.

Figure 4: The `Connection` Property s Accessibility Level Can Be Configured via the `ConnectionModifier` Property (Click to view full-size image)

Save the DataSet and then return to the `ProductsBLL` class. As before, go to one of the existing methods and type in `Adapter` and then hit the period key to bring up IntelliSense. The list should include a `Connection` property, meaning that you can now programmatically read or assign any connection-level settings from the BLL.

Step 3: Examining the Command-Related Properties

A TableAdapter consists of a main query that, by default, has auto-generated `INSERT`, `UPDATE`, and `DELETE` statements. This main query s `INSERT`, `UPDATE`, and `DELETE` statements are implemented in the TableAdapter s code as an ADO.NET data adapter object via the `Adapter` property. Like with its `Connection` property, the `Adapter` property s data type is determined by the data provider used. Since these tutorials use the SqlClient provider, the `Adapter` property is of type `SqlDataAdapter`.

The TableAdapter s `Adapter` property has three properties of type `SqlCommand` that it uses to issue the `INSERT`, `UPDATE`, and `DELETE` statements:

- `InsertCommand`
- `UpdateCommand`
- `DeleteCommand`

A `SqlCommand` object is responsible for sending a particular query to the database and has properties like: `CommandText`, which contains the ad-hoc SQL statement or stored procedure to execute; and `Parameters`, which is a collection of `SqlParameter` objects. As we saw back in the Creating a Data Access Layer tutorial, these command objects can be customized through the Properties window.

In addition to its main query, the TableAdapter can include a variable number of methods that, when invoked, dispatch a specified command to the database. The main query s command object and the command objects for all additional methods are stored in the TableAdapter s `CommandCollection` property.

Let s take a moment to look at the code generated by the `ProductsTableAdapter` in the `Northwind` DataSet for these two properties and their supporting member variables and helper methods:

```
private System.Data.SqlClient.SqlDataAdapter _adapter;
private void InitAdapter() {
    this._adapter = new System.Data.SqlClient.SqlDataAdapter();

    ... Code that creates the InsertCommand, UpdateCommand, ...
    ... and DeleteCommand instances - omitted for brevity ...
}
private System.Data.SqlClient.SqlDataAdapter Adapter {
    get {
        if ((this._adapter == null)) {
            this.InitAdapter();
        }
        return this._adapter;
    }
}
private System.Data.SqlClient.SqlCommand[] _commandCollection;
private void InitCommandCollection() {
    this._commandCollection = new System.Data.SqlClient.SqlCommand[9];
    ... Code that creates the command objects for the main query and the ...
    ... ProductsTableAdapter's other eight methods - omitted for brevity ...
}
protected System.Data.SqlClient.SqlCommand[] CommandCollection {
    get {
        if ((this._commandCollection == null)) {
            this.InitCommandCollection();
        }
        return this._commandCollection;
    }
}
```

The code for the `Adapter` and `CommandCollection` properties closely mimics that of the `Connection` property. There are member variables that hold the objects used by the properties. The properties `get` accessors start by checking to see if the corresponding member variable is `null`. If so, an initialization method is called which creates an instance of the member variable and assigns the core command-related properties.

Step 4: Exposing Command-Level Settings

Ideally, the command-level information should remain encapsulated within the Data Access Layer. Should this information be needed in other layers of the architecture, however, it can be exposed through a partial class, just like with the connection-level settings.

Since the TableAdapter only has a single `Connection` property, the code for exposing connection-level settings is fairly straightforward. Things are a bit more complicated when modifying command-level settings because the TableAdapter can have multiple command objects - an `InsertCommand`, `UpdateCommand`, and `DeleteCommand`, along with a variable number of command objects in the `CommandCollection` property. When updating command-level settings, these settings will need to be propagated to all of the command objects.

For example, imagine that there were certain queries in the TableAdapter that took an extraordinary long time to execute. When using the TableAdapter to execute one of those queries, we might want to increase the command object s `CommandTimeout` property. This property specifies the number of seconds to wait for the command to execute and defaults to 30.

To allow the `CommandTimeout` property to be adjusted by the BLL, add the following `public` method to the `ProductsDataTable` using the partial class file created in Step 2 (`ProductsTableAdapter.ConnectionAndCommandSettings.cs`):

```
public void SetCommandTimeout(int timeout)
{
    if (this.Adapter.InsertCommand != null)
        this.Adapter.InsertCommand.CommandTimeout = timeout;
    if (this.Adapter.DeleteCommand != null)
        this.Adapter.DeleteCommand.CommandTimeout = timeout;
    if (this.Adapter.UpdateCommand != null)
        this.Adapter.UpdateCommand.CommandTimeout = timeout;
    for (int i = 0; i < this.CommandCollection.Length; i++)
        if (this.CommandCollection[i] != null)
            this.CommandCollection[i].CommandTimeout = timeout;
}
```

This method could be invoked from the BLL or Presentation Layer to set the command timeout for all commands issues by that TableAdapter instance.

NOTE

The `Adapter` and `CommandCollection` properties are marked as `private`, meaning they can only be accessed from code within the TableAdapter. Unlike the `Connection` property, these access modifiers are not configurable. Therefore, if you need to expose command-level properties to other layers in the architecture you must use the partial class approach discussed above to provide a `public` method or property that reads or writes to the `private` command objects.

Summary

The TableAdapters within a Typed DataSet serve to encapsulate data access details and complexity. Using TableAdapters, we do not have to worry about writing ADO.NET code to connect to the database, issue a command, or populate the results into a DataTable. It is all handled automatically for us.

However, there may be times when we need to customize the low-level ADO.NET specifics, such as changing the connection string or the default connection or command timeout values. The TableAdapter has auto-generated `Connection`, `Adapter`, and `CommandCollection` properties, but these are either `internal` or `private`, by default. This internal information can be exposed by extending the TableAdapter using partial classes to include `public` methods or properties. Alternatively, the TableAdapter s `Connection` property access modifier can be configured through the TableAdapter s `ConnectionModifier` property.

Happy Programming!

Protecting Connection Strings and Other Configuration Information (C#)

2/20/2020 • 16 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

An ASP.NET application typically stores configuration information in a Web.config file. Some of this information is sensitive and warrants protection. By default this file will not be served to a Web site visitor, but an administrator or a hacker may gain access to the Web server's file system and view the contents of the file. In this tutorial we learn that ASP.NET 2.0 allows us to protect sensitive information by encrypting sections of the Web.config file.

Introduction

Configuration information for ASP.NET applications is commonly stored in an XML file named `Web.config`. Over the course of these tutorials we have updated the `Web.config` a handful of times. When creating the `Northwind` Typed DataSet in the first tutorial, for example, connection string information was automatically added to `Web.config` in the `<connectionStrings>` section. Later, in the Master Pages and Site Navigation tutorial, we manually updated `Web.config`, adding a `<pages>` element indicating that all of the ASP.NET pages in our project should use the `DataWebControls` Theme.

Since `Web.config` may contain sensitive data such as connection strings, it is important that the contents of `Web.config` be kept safe and hidden from unauthorized viewers. By default, any HTTP request to a file with the `.config` extension is handled by the ASP.NET engine, which returns the *This type of page is not served* message shown in Figure 1. This means that visitors cannot view your `Web.config` file s contents by simply entering http://www.YourServer.com/Web.config into their browser s Address bar.

Figure 1: Visiting `Web.config` Through a Browser Returns a This type of page is not served Message (Click to view full-size image)

But what if an attacker is able to find some other exploit that allows her to view your `Web.config` file s contents? What could an attacker do with this information, and what steps can be taken to further protect the sensitive information within `Web.config`? Fortunately, most sections in `Web.config` do not contain sensitive information. What harm can an attacker perpetrate if they know the name of the default Theme used by your ASP.NET pages?

Certain `Web.config` sections, however, contain sensitive information that may include connection strings, user

names, passwords, server names, encryption keys, and so forth. This information is typically found in the following `Web.config` sections:

- `<appSettings>`
- `<connectionStrings>`
- `<identity>`
- `<sessionState>`

In this tutorial we will look at techniques for protecting such sensitive configuration information. As we will see, the .NET Framework version 2.0 includes a protected configurations system that makes programmatically encrypting and decrypting selected configuration sections a breeze.

> **NOTE**
> This tutorial concludes with a look at Microsoft s recommendations for connecting to a database from an ASP.NET application. In addition to encrypting your connection strings, you can help harden your system by ensuring that you are connecting to the database in a secure fashion.

Step 1: Exploring ASP.NET 2.0 s Protected Configuration Options

ASP.NET 2.0 includes a protected configuration system for encrypting and decrypting configuration information. This includes methods in the .NET Framework that can be used to programmatically encrypt or decrypt configuration information. The protected configuration system uses the provider model, which allows developers to choose what cryptographic implementation is used.

The .NET Framework ships with two protected configuration providers:

- `RSAProtectedConfigurationProvider` - uses the asymmetric RSA algorithm for encryption and decryption.
- `DPAPIProtectedConfigurationProvider` - uses the Windows Data Protection API (DPAPI) for encryption and decryption.

Since the protected configuration system implements the provider design pattern, it is possible to create your own protected configuration provider and plug it into your application. See Implementing a Protected Configuration Provider for more information on this process.

The RSA and DPAPI providers use keys for their encryption and decryption routines, and these keys can be stored at the machine- or user-level. Machine-level keys are ideal for scenarios where the web application runs on its own dedicated server or if there are multiple applications on a server that need to share encrypted information. User-level keys are a more secure option in shared hosting environments where other applications on the same server should not be able to decrypt your application s protected configuration sections.

In this tutorial our examples will use the DPAPI provider and machine-level keys. Specifically, we will look at encrypting the `<connectionStrings>` section in `Web.config`, although the protected configuration system can be used to encrypt most any `Web.config` section. For information on using user-level keys or using the RSA provider, consult the resources in the Further Readings section at the end of this tutorial.

NOTE

The `RSAProtectedConfigurationProvider` and `DPAPIProtectedConfigurationProvider` providers are registered in the `machine.config` file with the provider names `RsaProtectedConfigurationProvider` and `DataProtectionConfigurationProvider`, respectively. When encrypting or decrypting configuration information we will need to supply the appropriate provider name (`RsaProtectedConfigurationProvider` or `DataProtectionConfigurationProvider`) rather than the actual type name (`RSAProtectedConfigurationProvider` and `DPAPIProtectedConfigurationProvider`). You can find the `machine.config` file in the `$WINDOWS$\Microsoft.NET\Framework\version\CONFIG` folder.

Step 2: Programmatically Encrypting and Decrypting Configuration Sections

With a few lines of code we can encrypt or decrypt a particular configuration section using a specified provider. The code, as we will see shortly, simply needs to programmatically reference the appropriate configuration section, call its `ProtectSection` or `UnprotectSection` method, and then call the `Save` method to persist the changes. Moreover, the .NET Framework includes a helpful command line utility that can encrypt and decrypt configuration information. We will explore this command line utility in Step 3.

To illustrate programmatically protecting configuration information, let s create an ASP.NET page that includes buttons for encrypting and decrypting the `<connectionStrings>` section in `Web.config`.

Start by opening the `EncryptingConfigSections.aspx` page in the `AdvancedDAL` folder. Drag a TextBox control from the Toolbox onto the Designer, setting its `ID` property to `WebConfigContents`, its `TextMode` property to `MultiLine`, and its `Width` and `Rows` properties to 95% and 15, respectively. This TextBox control will display the contents of `Web.config` allowing us to quickly see if the contents are encrypted or not. Of course, in a real application you would never want to display the contents of `Web.config`.

Beneath the TextBox, add two Button controls named `EncryptConnStrings` and `DecryptConnStrings`. Set their Text properties to Encrypt Connection Strings and Decrypt Connection Strings .

At this point your screen should look similar to Figure 2.

Figure 2: Add a TextBox and Two Button Web Controls to the Page (Click to view full-size image)

Next, we need to write code that loads and displays the contents of `Web.config` in the `WebConfigContents` TextBox when the page is first loaded. Add the following code to the page s code-behind class. This code adds a method named `DisplayWebConfig` and calls it from the `Page_Load` event handler when `Page.IsPostBack` is `false`:

```
protected void Page_Load(object sender, EventArgs e)
{
    // On the first page visit, call DisplayWebConfig method
    if (!Page.IsPostBack)
        DisplayWebConfig();
}
private void DisplayWebConfig()
{
    // Reads in the contents of Web.config and displays them in the TextBox
    StreamReader webConfigStream =
        File.OpenText(Path.Combine(Request.PhysicalApplicationPath, "Web.config"));
    string configContents = webConfigStream.ReadToEnd();
    webConfigStream.Close();
    WebConfigContents.Text = configContents;
}
```

The `DisplayWebConfig` method uses the `File` class to open the application s `Web.config` file, the `StreamReader` class to read its contents into a string, and the `Path` class to generate the physical path to the `Web.config` file. These three classes are all found in the `System.IO` namespace. Consequently, you will need to add a `using` `System.IO` statement to the top of the code-behind class or, alternatively, prefix these class names with `System.IO.` .

Next, we need to add event handlers for the two Button controls `Click` events and add the necessary code to encrypt and decrypt the `<connectionStrings>` section using a machine-level key with the DPAPI provider. From the Designer, double-click each of the Buttons to add a `Click` event handler in the code-behind class and then add the following code:

```
protected void EncryptConnStrings_Click(object sender, EventArgs e)
{
    // Get configuration information about Web.config
    Configuration config =
        WebConfigurationManager.OpenWebConfiguration(Request.ApplicationPath);
    // Let's work with the <connectionStrings> section
    ConfigurationSection connectionStrings = config.GetSection("connectionStrings");
    if (connectionStrings != null)
        // Only encrypt the section if it is not already protected
        if (!connectionStrings.SectionInformation.IsProtected)
        {
            // Encrypt the <connectionStrings> section using the
            // DataProtectionConfigurationProvider provider
            connectionStrings.SectionInformation.ProtectSection(
                "DataProtectionConfigurationProvider");
            config.Save();

            // Refresh the Web.config display
            DisplayWebConfig();
        }
}
protected void DecryptConnStrings_Click(object sender, EventArgs e)
{
    // Get configuration information about Web.config
    Configuration config =
        WebConfigurationManager.OpenWebConfiguration(Request.ApplicationPath);
    // Let's work with the <connectionStrings> section
    ConfigurationSection connectionStrings =
        config.GetSection("connectionStrings");
    if (connectionStrings != null)
        // Only decrypt the section if it is protected
        if (connectionStrings.SectionInformation.IsProtected)
        {
            // Decrypt the <connectionStrings> section
            connectionStrings.SectionInformation.UnprotectSection();
            config.Save();
            // Refresh the Web.config display
            DisplayWebConfig();
        }
}
```

The code used in the two event handlers is nearly identical. They both start by getting information about the current application s `Web.config` file via the `WebConfigurationManager` class s `OpenWebConfiguration` method. This method returns the web configuration file for the specified virtual path. Next, the `Web.config` file s `<connectionStrings>` section is accessed via the `Configuration` class s `GetSection(sectionName)` method, which returns a `ConfigurationSection` object.

The `ConfigurationSection` object includes a `SectionInformation` property that provides additional information and functionality regarding the configuration section. As the code above shows, we can determine whether the configuration section is encrypted by checking the `SectionInformation` property s `IsProtected` property. Moreover, the section can be encrypted or decrypted via the `SectionInformation` property s `ProtectSection(provider)` and `UnprotectSection` methods.

The `ProtectSection(provider)` method accepts as input a string specifying the name of the protected configuration provider to use when encrypting. In the `EncryptConnString` Button s event handler we pass DataProtectionConfigurationProvider into the `ProtectSection(provider)` method so that the DPAPI provider is used. The `UnprotectSection` method can determine the provider that was used to encrypt the configuration section and therefore does not require any input parameters.

After calling the `ProtectSection(provider)` or `UnprotectSection` method, you must call the `Configuration` object s `Save` method to persist the changes. Once the configuration information has been encrypted or decrypted and

the changes saved, we call `DisplayWebConfig` to load the updated `Web.config` contents into the TextBox control.

Once you have entered the above code, test it by visiting the `EncryptingConfigSections.aspx` page through a browser. You should initially see a page that lists the contents of `Web.config` with the `<connectionStrings>` section displayed in plain-text (see Figure 3).

Figure 3: Add a TextBox and Two Button Web Controls to the Page (Click to view full-size image)

Now click the Encrypt Connection Strings button. If request validation is enabled, the markup posted back from the `WebConfigContents` TextBox will produce an `HttpRequestValidationException`, which displays the message, A potentially dangerous `Request.Form` value was detected from the client. Request validation, which is enabled by default in ASP.NET 2.0, prohibits postbacks that include un-encoded HTML and is designed to help prevent script-injection attacks. This check can be disabled at the page- or application-level. To turn it off for this page, set the `ValidateRequest` setting to `false` in the `@Page` directive. The `@Page` directive is found at the top of the page s declarative markup.

```
<%@ Page ValidateRequest="False" ... %>
```

For more information on request validation, its purpose, how to disable it at the page- and application-level, as well as how to HTML encode markup, see Request Validation - Preventing Script Attacks.

After disabling request validation for the page, try clicking the Encrypt Connection Strings button again. On postback, the configuration file will be accessed and its `<connectionStrings>` section encrypted using the DPAPI provider. The TextBox is then updated to display the new `Web.config` content. As Figure 4 shows, the `<connectionStrings>` information is now encrypted.

Figure 4: Clicking the Encrypt Connection Strings Button Encrypts the `<connectionString>` Section (Click to view full-size image)

The encrypted `<connectionStrings>` section generated on my computer follows, although some of the content in the `<CipherData>` element has been removed for brevity:

```
<connectionStrings
    configProtectionProvider="DataProtectionConfigurationProvider">
  <EncryptedData>
    <CipherData>
      <CipherValue>AQAAANCMnd8BFdERjHoAwE/...zChw==</CipherValue>
    </CipherData>
  </EncryptedData>
</connectionStrings>
```

NOTE

The `<connectionStrings>` element specifies the provider used to perform the encryption (`DataProtectionConfigurationProvider`). This information is used by the `UnprotectSection` method when the Decrypt Connection Strings button is clicked.

When the connection string information is accessed from `Web.config` - either by code we write, from a SqlDataSource control, or the auto-generated code from the TableAdapters in our Typed DataSets - it is automatically decrypted. In short, we do not need to add any extra code or logic to decrypt the encrypted `<connectionString>` section. To demonstrate this, visit one of the earlier tutorials at this time, such as the Simple Display tutorial from the Basic Reporting section (`~/BasicReporting/SimpleDisplay.aspx`). As Figure 5 shows, the tutorial works exactly as we would expect it, indicating that the encrypted connection string information is being automatically decrypted by the ASP.NET page.

Figure 5: The Data Access Layer Automatically Decrypts the Connection String Information (Click to view full-size image)

To revert the `<connectionStrings>` section back to its plain-text representation, click the Decrypt Connection Strings button. On postback you should see the connection strings in `Web.config` in plain-text. At this point your screen should look like it did when first visiting this page (see in Figure 3).

Step 3: Encrypting Configuration Sections Using `aspnet_regiis.exe`

The .NET Framework includes a variety of command line tools in the `$WINDOWS$\Microsoft.NET\Framework\version\` folder. In the Using SQL Cache Dependencies tutorial, for instance, we looked at using the `aspnet_regsql.exe` command line tool to add the infrastructure necessary for SQL cache dependencies. Another useful command line tool in this folder is the ASP.NET IIS Registration tool (`aspnet_regiis.exe`). As its name implies, the ASP.NET IIS Registration tool is primarily used to register an ASP.NET 2.0 application with Microsoft s professional-grade Web server, IIS. In addition to its IIS-related features, the ASP.NET IIS Registration tool can also be used to encrypt or decrypt specified configuration sections in `Web.config`.

The following statement shows the general syntax used to encrypt a configuration section with the `aspnet_regiis.exe` command line tool:

```
aspnet_regiis.exe -pef section physical_directory -prov provider
```

section is the configuration section to encrypt (like connectionStrings), the *physical_directory* is the full, physical path to the web application s root directory, and *provider* is the name of the protected configuration provider to use (such as DataProtectionConfigurationProvider). Alternatively, if the web application is registered in IIS you can enter the virtual path instead of the physical path using the following syntax:

```
aspnet_regiis.exe -pe section -app virtual_directory -prov provider
```

The following `aspnet_regiis.exe` example encrypts the `<connectionStrings>` section using the DPAPI provider with a machine-level key:

```
aspnet_regiis.exe -pef
"connectionStrings" "C:\Websites\ASPNET_Data_Tutorial_73_CS"
-prov "DataProtectionConfigurationProvider"
```

Similarly, the `aspnet_regiis.exe` command line tool can be used to decrypt configuration sections. Instead of using the `-pef` switch, use `-pdf` (or instead of `-pe`, use `-pd`). Also, note that the provider name is not necessary when decrypting.

```
aspnet_regiis.exe -pdf section physical_directory
  -- or --
aspnet_regiis.exe -pd section -app virtual_directory
```

NOTE

Since we are using the DPAPI provider, which uses keys specific to the computer, you must run `aspnet_regiis.exe` from the same machine from which the web pages are being served. For example, if you run this command line program from your local development machine and then upload the encrypted Web.config file to the production server, the production server will not be able to decrypt the connection string information since it was encrypted using keys specific to your development machine. The RSA provider does not have this limitation as it is possible to export the RSA keys to another machine.

Understanding Database Authentication Options

Before any application can issue `SELECT`, `INSERT`, `UPDATE`, or `DELETE` queries to a Microsoft SQL Server database, the database first must identify the requestor. This process is known as *authentication* and SQL Server provides two methods of authentication:

- **Windows Authentication** - the process under which the application is running is used to communicate with the database. When running an ASP.NET application through Visual Studio 2005 s ASP.NET Development Server, the ASP.NET application assumes the identity of the currently logged on user. For ASP.NET applications on Microsoft Internet Information Server (IIS), ASP.NET applications usually assume the identity of `domainName``\MachineName` or `domainName``\NETWORK SERVICE`, although this can be customized.
- **SQL Authentication** - a user ID and password values are supplied as credentials for authentication. With SQL authentication, the user ID and password are provided in the connection string.

Windows authentication is preferred over SQL authentication because it is more secure. With Windows authentication the connection string is free from a username and password and if the web server and database server reside on two different machines, the credentials are not sent over the network in plain-text. With SQL authentication, however, the authentication credentials are hard-coded in the connection string and are transmitted from the web server to the database server in plain-text.

These tutorials have used Windows authentication. You can tell what authentication mode is being used by inspecting the connection string. The connection string in `Web.config` for our tutorials has been:

```
Data Source=.\SQLEXPRESS; AttachDbFilename=|DataDirectory|\NORTHWND.MDF; Integrated Security=True; User
Instance=True
```

The Integrated Security=True and lack of a username and password indicate that Windows authentication is being used. In some connection strings the term Trusted Connection=Yes or Integrated Security=SSPI is used instead of Integrated Security=True, but all three indicate the use of Windows authentication.

The following example shows a connection string that uses SQL authentication. Note the credentials embedded within the connection string:

```
Server=serverName; Database=Northwind; uid=userID; pwd=password
```

Imagine that an attacker is able to view your application s `Web.config` file. If you use SQL authentication to connect to a database that is accessible over the Internet, the attacker can use this connection string to connect to your database through SQL Management Studio or from ASP.NET pages on their own website. To help mitigate this threat, encrypt the connection string information in `Web.config` using the protected configuration system.

> **NOTE**
> For more information on the different types of authentication available in SQL Server, see Building Secure ASP.NET Applications: Authentication, Authorization, and Secure Communication. For further connection string examples illustrating the differences between Windows and SQL authentication syntax, refer to ConnectionStrings.com.

Summary

By default, files with a `.config` extension in an ASP.NET application cannot be accessed through a browser. These types of files are not returned because they may contain sensitive information, such as database connection strings, usernames and passwords, and so on. The protected configuration system in .NET 2.0 helps further protect sensitive information by allowing specified configuration sections to be encrypted. There are two built-in protected configuration providers: one that uses the RSA algorithm and one that uses the Windows Data Protection API (DPAPI).

In this tutorial we looked at how to encrypt and decrypt configuration settings using the DPAPI provider. This can be accomplished both programmatically, as we saw in Step 2, as well as through the `aspnet_regiis.exe` command line tool, which was covered in Step 3. For more information on using user-level keys or using the RSA provider instead, see the resources in the Further Reading section.

Happy Programming!

Debugging Stored Procedures (C#)

2/20/2020 • 14 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

Visual Studio Professional and Team System editions allow you to set breakpoints and step in to stored procedures within SQL Server, making debugging stored procedures as easy as debugging application code. This tutorial demonstrates direct database debugging and application debugging of stored procedures.

Introduction

Visual Studio provides a rich debugging experience. With a few keystrokes or clicks of the mouse, it s possible to use breakpoints to stop execution of a program and examine its state and control flow. Along with debugging application code, Visual Studio offers support for debugging stored procedures from within SQL Server. Just like breakpoints can be set within the code of an ASP.NET code-behind class or Business Logic Layer class, so too can they be placed within stored procedures.

In this tutorial we will look at stepping into stored procedures from the Server Explorer within Visual Studio as well as how to set breakpoints that are hit when the stored procedure is called from the running ASP.NET application.

> **NOTE**
> Unfortunately, stored procedures can only be stepped into and debugged through the Professional and Team Systems versions of Visual Studio. If you are using Visual Web Developer or the standard version of Visual Studio, you are welcome to read along as we walk through the steps necessary to debug stored procedures, but you will not be able to replicate these steps on your machine.

SQL Server Debugging Concepts

Microsoft SQL Server 2005 was designed to provide integration with the Common Language Runtime (CLR), which is the runtime used by all .NET assemblies. Consequently, SQL Server 2005 supports managed database objects. That is, you can create database objects like stored procedures and User-Defined Functions (UDFs) as methods in a C# class. This enables these stored procedures and UDFs to utilize functionality in the .NET Framework and from your own custom classes. Of course, SQL Server 2005 also provides support for T-SQL database objects.

SQL Server 2005 offers debugging support for both T-SQL and managed database objects. However, these objects can only be debugged through Visual Studio 2005 Professional and Team Systems editions. In this tutorial we will examine debugging T-SQL database objects. The subsequent tutorial looks at debugging managed database objects.

The Overview of T-SQL and CLR Debugging in SQL Server 2005 blog entry from the SQL Server 2005 CLR Integration team highlights the three ways to debug SQL Server 2005 objects from Visual Studio:

- **Direct Database Debugging (DDD)** - from Server Explorer we can step into any T-SQL database object, such as stored procedures and UDFs. We will examine DDD in Step 1.
- **Application Debugging** - we can set breakpoints within a database object and then run our ASP.NET application. When the database object is executed, the breakpoint will be hit and control turned over to the

debugger. Note that with application debugging we cannot step into a database object from application code. We must explicitly set breakpoints in those stored procedures or UDFs where we want the debugger to stop. Application debugging is examined starting in Step 2.

- **Debugging from a SQL Server Project** - Visual Studio Professional and Team Systems editions include a SQL Server Project type that is commonly used to create managed database objects. We will examine using SQL Server Projects and debugging their contents in the next tutorial.

Visual Studio can debug stored procedures on local and remote SQL Server instances. A local SQL Server instance is one that is installed on the same machine as Visual Studio. If the SQL Server database you are using is not located on your development machine, then it is considered a remote instance. For these tutorials we have been using local SQL Server instances. Debugging stored procedures on a remote SQL server instance requires more configuration steps than when debugging stored procedures on a local instance.

If you are using a local SQL Server instance, you can start with Step 1 and work through this tutorial to the end. If you are using a remote SQL Server instance, however, you will first need to ensure that when debugging you are logged to your development machine with a Windows user account that has a SQL Server login on the remote instance. Moreover, both this database login and the database login used to connect to the database from the running ASP.NET application must be members of the `sysadmin` role. See the Debugging T-SQL Database Objects on Remote Instances section at the end of this tutorial for more information on configuring Visual Studio and SQL Server to debug a remote instance.

Finally, understand that debugging support for T-SQL database objects is not as feature rich as debugging support for .NET applications. For example, breakpoint conditions and filters are not supported, only a subset of the debugging windows are available, you cannot use Edit and Continue, the Immediate window is rendered useless, and so forth. See Limitations on Debugger Commands and Features for more information.

Step 1: Directly Stepping Into a Stored Procedure

Visual Studio makes it easy to directly debug a database object. Let s look at how to use the Direct Database Debugging (DDD) feature to step into the `Products_SelectByCategoryID` stored procedure in the Northwind database. As its name implies, `Products_SelectByCategoryID` returns product information for a particular category; it was created in the Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorial. Start by going to the Server Explorer and expand the Northwind database node. Next, drill down into the Stored Procedures folder, right-click on the `Products_SelectByCategoryID` stored procedure, and choose the Step Into Stored Procedure option from the context menu. This will start the debugger.

Since the `Products_SelectByCategoryID` stored procedure expects a `@CategoryID` input parameter, we are asked to provide this value. Enter 1, which will return information about the beverages.

Figure 1: Use the Value 1 for the `@CategoryID` Parameter

After supplying the value for the `@CategoryID` parameter, the stored procedure is executed. Rather than running to completion, though, the debugger halts execution on the first statement. Note the yellow arrow in the margin, indicating the current location in the stored procedure. You can view and edit parameter values through the Watch window or by hovering over the parameter name in the stored procedure.

Figure 2: The Debugger has Halted on the First Statement of the Stored Procedure (Click to view full-size image)

To step through the stored procedure one statement at a time, click the Step Over button in the Toolbar or hit the F10 key. The `Products_SelectByCategoryID` stored procedure contains a single `SELECT` statement, so hitting F10 will Step over the single statement and complete the execution of the stored procedure. After the stored procedure has completed, its output will appear in the Output window and the debugger will terminate.

> **NOTE**
>
> T-SQL debugging occurs at the statement level; you cannot Step into a `SELECT` statement.

Step 2: Configuring the Website for Application Debugging

While debugging a stored procedure directly from the Server Explorer is handy, in many scenarios we are more interested in debugging the stored procedure when it is called from our ASP.NET application. We can add breakpoints to a stored procedure from within Visual Studio and then start debugging the ASP.NET application. When a stored procedure with breakpoints is invoked from the application, execution will halt at the breakpoint and we can view and change the stored procedure s parameter values and step through its statements, just like we did in Step 1.

Before we can start debugging stored procedures called from the application, we need to instruct the ASP.NET web application to integrate with the SQL Server debugger. Start by right-clicking on the website name in the Solution Explorer (`ASPNET_Data_Tutorial_74_CS`). Choose the Property Pages option from the context menu, select the Start Options item on the left, and check the SQL Server checkbox in the Debuggers section (see Figure 3).

Figure 3: Check the SQL Server Checkbox in the Application s Property Pages (Click to view full-size image)

Additionally, we need to update the database connection string used by the application so that connection pooling is disabled. When a connection to a database is closed, the corresponding `SqlConnection` object is placed in a pool of available connections. When establishing a connection to a database, an available connection object can be retrieved from this pool rather than having to create and establish a new connection. This pooling of connection objects is a performance enhancement and is enabled by default. However, when debugging we want to turn off connection pooling because the debugging infrastructure is not correctly reestablished when working with a connection that was taken from the pool.

To disabled connection pooling, update the `NORTHWNDConnectionString` in `Web.config` so that it includes the setting `Pooling=false` .

```
<connectionStrings>
    <add name="NORTHWNDConnectionString" connectionString=
        "Data Source=.\SQLEXPRESS;AttachDbFilename=|DataDirectory|\NORTHWND.MDF;
            Integrated Security=True;User Instance=True;Pooling=false"
        providerName="System.Data.SqlClient" />
</connectionStrings>
```

NOTE

Once you have finished debugging SQL Server through the ASP.NET application be sure to reinstate connection pooling by removing the `Pooling` setting from the connection string (or by setting it to `Pooling=true`).

At this point the ASP.NET application has been configured to allow Visual Studio to debug SQL Server database objects when invoked through the web application. All that remains now is to add a breakpoint to a stored procedure and start debugging!

Step 3: Adding a Breakpoint and Debugging

Open the `Products_SelectByCategoryID` stored procedure and set a breakpoint at the start of the `SELECT` statement by clicking in the margin at the appropriate place or by placing your cursor at the start of the `SELECT` statement and hitting F9. As Figure 4 illustrates, the breakpoint appears as a red circle in the margin.

Figure 4: Set a Breakpoint in the `Products_SelectByCategoryID` Stored Procedure (Click to view full-size image)

In order for a SQL database object to be debugged through a client application, it is imperative that the database be configured to support application debugging. When you first set a breakpoint, this setting should automatically be switched on, but it is prudent to double-check. Right-click on the `NORTHWND.MDF` node in the Server Explorer. The context menu should include a checked menu item named Application Debugging .

Figure 5: Ensure that the Application Debugging Option is Enabled

With the breakpoint set and the Application Debugging option enabled, we are ready to debug the stored procedure when called from the ASP.NET application. Start the debugger by going to the Debug menu and choosing Start Debugging, by hitting F5, or by clicking the green play icon in the Toolbar. This will start the debugger and launch the website.

The `Products_SelectByCategoryID` stored procedure was created in the Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorial. Its corresponding web page (`~/AdvancedDAL/ExistingSprocs.aspx`) contains a GridView that displays the results returned by this stored procedure. Visit this page through the browser. Upon reaching the page, the breakpoint in the `Products_SelectByCategoryID` stored procedure will be hit and control returned to Visual Studio. Just like in Step 1, you can step through the stored procedure s statements and view and modify the parameter values.

Figure 6: The `ExistingSprocs.aspx` Page Initially Displays the Beverages (Click to view full-size image)

Figure 7: The Stored Procedure s Breakpoint has been Reached (Click to view full-size image)

As the Watch window in Figure 7 shows, the value of the `@CategoryID` parameter is 1. This is because the `ExistingSprocs.aspx` page initially displays products in the beverages category, which has a `CategoryID` value of 1. Choose a different category from the drop-down list. Doing so causes a postback and re-executes the `Products_SelectByCategoryID` stored procedure. The breakpoint is hit again, but this time the `@CategoryID` parameter s value reflects the selected drop-down list item s `CategoryID`.

Figure 8: Choose a Different Category from the Drop-Down List (Click to view full-size image)

Figure 9: The `@CategoryID` Parameter Reflects the Category Selected from the Web Page (Click to view full-size image)

> **NOTE**
>
> If the breakpoint in the `Products_SelectByCategoryID` stored procedure is not hit when visiting the `ExistingSprocs.aspx` page, make sure that the SQL Server checkbox has been checked in the Debuggers section of the ASP.NET application s Properties Page, that connection pooling has been disabled, and that the database s Application Debugging option is enabled. If you re still having problems, restart Visual Studio and try again.

Debugging T-SQL Database Objects on Remote Instances

Debugging database objects through Visual Studio is fairly straightforward when the SQL Server database instance is on the same machine as Visual Studio. However, if SQL Server and Visual Studio reside on different machines then some careful configuration is required to get everything working properly. There are two core tasks we are faced with:

- Ensure that the login used to connect to the database via ADO.NET belongs to the `sysadmin` role.
- Ensure that the Windows user account used by Visual Studio on the development machine is a valid SQL

Server login account that belongs to the `sysadmin` role.

The first step is relatively straightforward. First, identify the user account used to connect to the database from the ASP.NET application and then, from SQL Server Management Studio, add that login account to the `sysadmin` role.

The second task requires that the Windows user account you use to debug the application be a valid login on the remote database. However, chances are the Windows account you logged on to your workstation with is not a valid login on SQL Server. Rather than adding your particular login account to SQL Server, a better choice would be to designate some Windows user account as the SQL Server debugging account. Then, to debug the database objects of a remote SQL Server instance, you would run Visual Studio using that Windows login account s credentials.

An example should help clarify things. Imagine that there is a Windows account named `SQLDebug` within the Windows domain. This account would need to be added to the remote SQL Server instance as a valid login and as a member of the `sysadmin` role. Then, to debug the remote SQL Server instance from Visual Studio, we would need to run Visual Studio as the `SQLDebug` user. This could be done by logging out of our workstation, logging back in as `SQLDebug`, and then launching Visual Studio, but a simpler approach would be to login to our workstation using our own credentials and then use `runas.exe` to launch Visual Studio as the `SQLDebug` user. `runas.exe` allows a particular application to be executed under the guise of a different user account. To launch Visual Studio as `SQLDebug`, you could enter the following statement at the command line:

```
runas.exe /user:SQLDebug "%PROGRAMFILES%\Microsoft Visual Studio 8\Common7\IDE\devenv.exe"
```

For a more detailed explanation on this process, see William R. Vaughn s *Hitchhiker s Guide to Visual Studio and SQL Server, Seventh Edition* as well as How To: Set SQL Server Permissions for Debugging.

> **NOTE**
> If your development machine is running Windows XP Service Pack 2 you will need to configure the Internet Connection Firewall to allow remote debugging. The How To: Enable SQL Server 2005 Debugging article notes that this involves two steps: (a) On the Visual Studio host machine, you must add `Devenv.exe` to the Exceptions list and open the TCP 135 port; and (b) On the remote (SQL) machine, you must open the TCP 135 port and add `sqlservr.exe` to the Exceptions list. If your domain policy requires network communication to be done through IPSec, you must open the UDP 4500 and UDP 500 ports.

Summary

In addition to providing debugging support for .NET application code, Visual Studio also provides a variety of debugging options for SQL Server 2005. In this tutorial we looked at two of those options: Direct Database Debugging and application debugging. To directly debug a T-SQL database object, locate the object through the Server Explorer then right-click on it and choose Step Into. This starts the debugger and halts on the first statement in the database object, at which point you can step through the object s statements and view and modify parameter values. In Step 1 we used this approach to step into the `Products_SelectByCategoryID` stored procedure.

Application debugging allows breakpoints to be set directly within the database objects. When a database object with breakpoints is invoked from a client application (such as an ASP.NET web application), the program halts as the debugger takes over. Application debugging is useful because it more clearly shows what application action causes a particular database object to be invoked. However, it requires a bit more configuration and setup than Direct Database Debugging.

Database objects can also be debugged through SQL Server Projects. We will look at using SQL Server Projects

and how to use them to create and debug managed database objects in the next tutorial.

Happy Programming!

Creating Stored Procedures and User-Defined Functions with Managed Code (C#)

9/16/2020 • 36 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

Microsoft SQL Server 2005 integrates with the .NET Common Language Runtime to allow developers to create database objects through managed code. This tutorial shows how to create managed stored procedures and managed user-defined functions with your Visual Basic or C# code. We also see how these editions of Visual Studio allow you to debug such managed database objects.

Introduction

Databases like Microsoft s SQL Server 2005 use the Transact-Structured Query Language (T-SQL) for inserting, modifying, and retrieving data. Most database systems include constructs for grouping a series of SQL statements that can then be executed as a single, reusable unit. Stored procedures are one example. Another is *User-Defined Functions*(UDFs), a construct that we will examine in greater detail in Step 9.

At its core, SQL is designed for working with sets of data. The `SELECT`, `UPDATE`, and `DELETE` statements inherently apply to all records in the corresponding table and are only limited by their `WHERE` clauses. Yet there are many language features designed for working with one record at a time and for manipulating scalar data. `CURSOR` s allow for a set of records to be looped through one at a time. String manipulation functions like `LEFT`, `CHARINDEX`, and `PATINDEX` work with scalar data. SQL also includes control flow statements like `IF` and `WHILE`.

Prior to Microsoft SQL Server 2005, stored procedures and UDFs could only be defined as a collection of T-SQL statements. SQL Server 2005, however, was designed to provide integration with the Common Language Runtime (CLR), which is the runtime used by all .NET assemblies. Consequently, the stored procedures and UDFs in a SQL Server 2005 database can be created using managed code. That is, you can create a stored procedure or UDF as a method in a C# class. This enables these stored procedures and UDFs to utilize functionality in the .NET Framework and from your own custom classes.

In this tutorial we will examine how to create managed stored procedures and User-Defined Functions and how to integrate them into our Northwind database. Let s get started!

> **NOTE**
> Managed database objects offer some advantages over their SQL counterparts. Language richness and familiarity and the ability to reuse existing code and logic are the main advantages. But managed database objects are likely to be less efficient when working with sets of data that do not involve much procedural logic. For a more thorough discussion on the advantages of using managed code versus T-SQL, check out the Advantages of Using Managed Code to Create Database Objects.

Step 1: Moving the Northwind Database Out of `App_Data`

All of our tutorials thus far have used a Microsoft SQL Server 2005 Express Edition database file in the web application s `App_Data` folder. Placing the database in `App_Data` simplified distributing and running these tutorials as all of the files were located within one directory and required no additional configuration steps to test the

tutorial.

For this tutorial, however, let s move the Northwind database out of `App_Data` and explicitly register it with the SQL Server 2005 Express Edition database instance. While we can perform the steps for this tutorial with the database in the `App_Data` folder, a number of the steps are made much simpler by explicitly registering the database with the SQL Server 2005 Express Edition database instance.

The download for this tutorial has the two database files - `NORTHWND.MDF` and `NORTHWND_log.LDF` - placed in a folder named `DataFiles`. If you are following along with your own implementation of the tutorials, close Visual Studio and move the `NORTHWND.MDF` and `NORTHWND_log.LDF` files from the website s `App_Data` folder to a folder outside of the website. Once the database files have been moved to another folder we need to register the Northwind database with the SQL Server 2005 Express Edition database instance. This can be done from SQL Server Management Studio. If you have a non-Express Edition of SQL Server 2005 installed on your computer then you likely already have Management Studio installed. If you only have SQL Server 2005 Express Edition on your computer then take a moment to download and install Microsoft SQL Server Management Studio Express.

Launch SQL Server Management Studio. As Figure 1 shows, Management Studio starts by asking what server to connect to. Enter localhost\SQLExpress for the server name, choose Windows Authentication in the Authentication drop-down list, and click Connect.

Figure 1: Connect to the Appropriate Database Instance

Once you ve connected, the Object Explorer window will list information about the SQL Server 2005 Express Edition database instance, including its databases, security information, management options, and so forth.

We need to attach the Northwind database in the `DataFiles` folder (or wherever you may have moved it) to the SQL Server 2005 Express Edition database instance. Right-click on the Databases folder and choose the Attach option from the context menu. This will bring up the Attach Databases dialog box. Click the Add button, drill down to the appropriate `NORTHWND.MDF` file, and click OK. At this point your screen should look similar to Figure 2.

Figure 2: Connect to the Appropriate Database Instance (Click to view full-size image)

> **NOTE**
>
> When connecting to the SQL Server 2005 Express Edition instance through Management Studio the Attach Databases dialog box does not allow you to drill down into user profile directories, such as My Documents. Therefore, make sure to place the `NORTHWND.MDF` and `NORTHWND_log.LDF` files in a non-user profile directory.

Click the OK button to attach the database. The Attach Databases dialog box will close and the Object Explorer should now list the just-attached database. Chances are the Northwind database has a name like

```
9FE54661B32FDD967F51D71D0D5145CC_LINE ARTICLES\DATATUTORIALS\VOLUME
3\CSHARP\73\ASPNET_DATA_TUTORIAL_75_CS\APP_DATA\NORTHWND.MDF
```

. Rename the database to Northwind by right-clicking on the database and choosing Rename.

Figure 3: Rename the Database to Northwind

Step 2: Creating a New Solution and SQL Server Project in Visual Studio

To create managed stored procedures or UDFs in SQL Server 2005 we will write the stored procedure and UDF logic as C# code in a class. Once the code has been written, we will need to compile this class into an assembly (a `.dll` file), register the assembly with the SQL Server database, and then create a stored procedure or UDF object in the database that points to the corresponding method in the assembly. These steps can all be performed manually. We can create the code in any text editor, compile it from the command line using the C# compiler (`csc.exe`), register it with the database using the `CREATE ASSEMBLY` command or from Management Studio, and add the stored procedure or UDF object through similar means. Fortunately, the Professional and Team Systems versions of Visual Studio include a SQL Server Project type that automates these tasks. In this tutorial we will walk through using the SQL Server Project type to create a managed stored procedure and UDF.

> **NOTE**
>
> If you are using Visual Web Developer or the Standard edition of Visual Studio, then you will have to use the manual approach instead. Step 13 provides detailed instructions for performing these steps manually. I encourage you to read Steps 2 through 12 before reading Step 13 since these steps include important SQL Server configuration instructions that must be applied regardless of what version of Visual Studio you are using.

Start by opening Visual Studio. From the File menu, choose New Project to display the New Project dialog box (see Figure 4). Drill down to the Database project type and then, from the Templates listed on the right, choose to create a new SQL Server Project. I have chosen to name this project `ManagedDatabaseConstructs` and placed it within a Solution named `Tutorial75`.

Figure 4: Create a New SQL Server Project (Click to view full-size image)

Click the OK button in the New Project dialog box to create the Solution and SQL Server Project.

A SQL Server Project is tied to a particular database. Consequently, after creating the new SQL Server Project we are immediately asked to specify this information. Figure 5 shows the New Database Reference dialog box that has been filled out to point to the Northwind database we registered in the SQL Server 2005 Express Edition database instance back in Step 1.

Figure 5: Associate the SQL Server Project with the Northwind Database

In order to debug the managed stored procedures and UDFs we will create within this project, we need to enable SQL/CLR debugging support for the connection. Whenever associating a SQL Server Project with a new database (as we did in Figure 5), Visual Studio asks us if we want to enable SQL/CLR debugging on the connection (see Figure 6). Click Yes.

Figure 6: Enable SQL/CLR Debugging

At this point the new SQL Server Project has been added to the Solution. It contains a folder named `Test Scripts` with a file named `Test.sql`, which is used for debugging the managed database objects created in the project. We will look at debugging in Step 12.

We can now add new managed stored procedures and UDFs to this project, but before we do let s first include our existing web application in the Solution. From the File menu select the Add option and choose Existing Web Site. Browse to the appropriate website folder and click OK. As Figure 7 shows, this will update the Solution to include two projects: the website and the `ManagedDatabaseConstructs` SQL Server Project.

Figure 7: The Solution Explorer Now Includes Two Projects

The `NORTHWNDConnectionString` value in `Web.config` currently references the `NORTHWND.MDF` file in the `App_Data` folder. Since we removed this database from `App_Data` and explicitly registered it in the SQL Server 2005 Express Edition database instance, we need to correspondingly update the `NORTHWNDConnectionString` value. Open the `Web.config` file in the website and change the `NORTHWNDConnectionString` value so that the connection string reads: `Data Source=localhost\SQLExpress;Initial Catalog=Northwind;Integrated Security=True`. After this change, your `<connectionStrings>` section in `Web.config` should look similar to the following:

```
<connectionStrings>
    <add name="NORTHWNDConnectionString" connectionString=
        "Data Source=localhost\SQLExpress;Initial Catalog=Northwind;
            Integrated Security=True;Pooling=false"
        providerName="System.Data.SqlClient" />
</connectionStrings>
```

> **NOTE**
>
> As discussed in the preceding tutorial, when debugging a SQL Server object from a client application, such as an ASP.NET website, we need to disable connection pooling. The connection string shown above disables connection pooling (`Pooling=false`). If you do not plan on debugging the managed stored procedures and UDFs from the ASP.NET website, enable connection pooling.

Step 3: Creating a Managed Stored Procedure

To add a managed stored procedure to the Northwind database we first need to create the stored procedure as a method in the SQL Server Project. From the Solution Explorer, right-click on the `ManagedDatabaseConstructs` project name and choose to add a new item. This will display the Add New Item dialog box, which lists the types of managed database objects that can be added to the project. As Figure 8 shows, this includes stored procedures and User-Defined Functions, among others.

Let s start by adding a stored procedure that simply returns all of the products that have been discontinued. Name the new stored procedure file `GetDiscontinuedProducts.cs`.

Figure 8: Add a New Stored Procedure Named `GetDiscontinuedProducts.cs` (Click to view full-size image)

This will create a new C# class file with the following content:

```
using System;
using System.Data;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;
public partial class StoredProcedures
{
    [Microsoft.SqlServer.Server.SqlProcedure]
    public static void GetDiscontinuedProducts()
    {
        // Put your code here
    }
};
```

Note that the stored procedure is implemented as a `static` method within a `partial` class file named `StoredProcedures`. Moreover, the `GetDiscontinuedProducts` method is decorated with the `SqlProcedure attribute`, which marks the method as a stored procedure.

The following code creates a `SqlCommand` object and sets its `CommandText` to a `SELECT` query that returns all of the columns from the `Products` table for products whose `Discontinued` field equals 1. It then executes the command and sends the results back to the client application. Add this code to the `GetDiscontinuedProducts` method.

```
// Create the command
SqlCommand myCommand = new SqlCommand();
myCommand.CommandText =
      @"SELECT ProductID, ProductName, SupplierID, CategoryID,
               QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
               ReorderLevel, Discontinued
        FROM Products
        WHERE Discontinued = 1";
// Execute the command and send back the results
SqlContext.Pipe.ExecuteAndSend(myCommand);
```

All managed database objects have access to a `SqlContext` object that represents the context of the caller. The `SqlContext` provides access to a `SqlPipe` object via its `Pipe` property. This `SqlPipe` object is used to ferry information between the SQL Server database and the calling application. As its name implies, the `ExecuteAndSend` method executes a passed-in `SqlCommand` object and sends the results back to the client application.

> **NOTE**
> Managed database objects are best suited for stored procedures and UDFs that use procedural logic rather than set-based logic. Procedural logic involves working with sets of data on a row-by-row basis or working with scalar data. The `GetDiscontinuedProducts` method we just created, however, involves no procedural logic. Therefore, it would ideally be implemented as a T-SQL stored procedure. It is implemented as a managed stored procedure to demonstrate the steps necessary for creating and deploying managed stored procedures.

Step 4: Deploying the Managed Stored Procedure

With this code complete, we are ready to deploy it to the Northwind database. Deploying a SQL Server Project compiles the code into an assembly, registers the assembly with the database, and creates the corresponding objects in the database, linking them to the appropriate methods in the assembly. The exact set of tasks performed by the Deploy option is more precisely spelled out in Step 13. Right-click on the `ManagedDatabaseConstructs` project name in the Solution Explorer and choose the Deploy option. However, deployment fails with the following error: Incorrect syntax near 'EXTERNAL'. You may need to set the compatibility level of the current database to a higher value to enable this feature. See help for the stored procedure `sp_dbcmptlevel`.

This error message occurs when attempting to register the assembly with the Northwind database. In order to register an assembly with a SQL Server 2005 database, the database s compatibility level must be set to 90. By default, new SQL Server 2005 databases have a compatibility level of 90. However, databases created using Microsoft SQL Server 2000 have a default compatibility level of 80. Since the Northwind database was initially a Microsoft SQL Server 2000 database, its compatibility level is currently set to 80 and therefore needs to be increased to 90 in order to register managed database objects.

To update the database s compatibility level, open a New Query window in Management Studio and enter:

```
exec sp_dbcmptlevel 'Northwind', 90
```

Click the Execute icon in the Toolbar to run the above query.

Figure 9: Update the Northwind Database s Compatibility Level (Click to view full-size image)

After updating the compatibility level, redeploy the SQL Server Project. This time the deployment should complete without error.

Return to SQL Server Management Studio, right-click on the Northwind database in the Object Explorer, and choose Refresh. Next, drill down into the Programmability folder and then expand the Assemblies folder. As Figure 10 shows, the Northwind database now includes the assembly generated by the `ManagedDatabaseConstructs` project.

Figure 10: The `ManagedDatabaseConstructs` Assembly is Now Registered with the Northwind Database

Also expand the Stored Procedures folder. There you will see a stored procedure named `GetDiscontinuedProducts`. This stored procedure was created by the deployment process and points to the `GetDiscontinuedProducts` method in the `ManagedDatabaseConstructs` assembly. When the `GetDiscontinuedProducts` stored procedure is executed, it, in turn, executes the `GetDiscontinuedProducts` method. Since this is a managed stored procedure it cannot be

edited through Management Studio (hence the lock icon next to the stored procedure name).

Figure 11: The `GetDiscontinuedProducts` Stored Procedure is Listed in the Stored Procedures Folder

There is still one more hurdle we have to overcome before we can call the managed stored procedure: the database is configured to prevent execution of managed code. Verify this by opening a new query window and executing the `GetDiscontinuedProducts` stored procedure. You will receive the following error message: Execution of user code in the .NET Framework is disabled. Enable 'clr enabled configuration option.

To examine the Northwind database s configuration information, enter and execute the command `exec sp_configure` in the query window. This shows that the clr enabled setting is currently set to 0.

Figure 12: The clr enabled Setting is Currently Set to 0 (Click to view full-size image)

Note that each configuration setting in Figure 12 has four values listed with it: the minimum and maximum values

and the config and run values. To update the config value for the clr enabled setting, execute the following command:

```
exec sp_configure 'clr enabled', 1
```

If you re-run the `exec sp_configure` you will see that the above statement updated the clr enabled setting s config value to 1, but that the run value is still set to 0. For this configuration change to take affect we need to execute the `RECONFIGURE` command, which will set the run value to the current config value. Simply enter `RECONFIGURE` in the query window and click the Execute icon in the Toolbar. If you run `exec sp_configure` now you should see a value of 1 for the clr enabled setting s config and run values.

With the clr enabled configuration complete, we are ready to run the managed `GetDiscontinuedProducts` stored procedure. In the query window enter and execute the command `exec` `GetDiscontinuedProducts`. Invoking the stored procedure causes the corresponding managed code in the `GetDiscontinuedProducts` method to execute. This code issues a `SELECT` query to return all products that are discontinued and returns this data to the calling application, which is SQL Server Management Studio in this instance. Management Studio receives these results and displays them in the Results window.

Figure 13: The `GetDiscontinuedProducts` Stored Procedure Returns All Discontinued Products (Click to view full-size image)

Step 5: Creating Managed Stored Procedures that Accept Input Parameters

Many of the queries and stored procedures we have created throughout these tutorials have used *parameters*. For example, in the Creating New Stored Procedures for the Typed DataSet s TableAdapters tutorial we created a stored procedure named `GetProductsByCategoryID` that accepted an input parameter named `@CategoryID`. The stored procedure then returned all products whose `CategoryID` field matched the value of the supplied `@CategoryID` parameter.

To create a managed stored procedure that accepts input parameters, simply specify those parameters in the method s definition. To illustrate this, let s add another managed stored procedure to the `ManagedDatabaseConstructs` project named `GetProductsWithPriceLessThan`. This managed stored procedure will accept an input parameter specifying a price and will return all products whose `UnitPrice` field is less than the parameter s value.

To add a new stored procedure to the project, right-click on the `ManagedDatabaseConstructs` project name and choose to add a new stored procedure. Name the file `GetProductsWithPriceLessThan.cs`. As we saw in Step 3, this will create a new C# class file with a method named `GetProductsWithPriceLessThan` placed within the `partial` class `StoredProcedures`.

Update the `GetProductsWithPriceLessThan` method s definition so that it accepts a `SqlMoney` input parameter

named `price` and write the code to execute and return the query results:

```
[Microsoft.SqlServer.Server.SqlProcedure]
public static void GetProductsWithPriceLessThan(SqlMoney price)
{
    // Create the command
    SqlCommand myCommand = new SqlCommand();
    myCommand.CommandText =
          @"SELECT ProductID, ProductName, SupplierID, CategoryID,
                   QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
                   ReorderLevel, Discontinued
            FROM Products
            WHERE UnitPrice < @MaxPrice";
    myCommand.Parameters.AddWithValue("@MaxPrice", price);
    // Execute the command and send back the results
    SqlContext.Pipe.ExecuteAndSend(myCommand);
}
```

The `GetProductsWithPriceLessThan` method s definition and code closely resembles the definition and code of the `GetDiscontinuedProducts` method created in Step 3. The only differences are that the `GetProductsWithPriceLessThan` method accepts as input parameter (`price`), the `SqlCommand` s query includes a parameter (`@MaxPrice`), and a parameter is added to the `SqlCommand` s `Parameters` collection is and assigned the value of the `price` variable.

After adding this code, redeploy the SQL Server Project. Next, return to SQL Server Management Studio and Refresh the Stored Procedures folder. You should see a new entry, `GetProductsWithPriceLessThan`. From a query window, enter and execute the command `exec GetProductsWithPriceLessThan 25`, which will list all products less than $25, as Figure 14 shows.

Figure 14: Products Under $25 are Displayed (Click to view full-size image)

Step 6: Calling the Managed Stored Procedure from the Data Access Layer

At this point we have added the `GetDiscontinuedProducts` and `GetProductsWithPriceLessThan` managed stored procedures to the `ManagedDatabaseConstructs` project and have registered them with the Northwind SQL Server database. We also invoked these managed stored procedures from SQL Server Management Studio (see Figure s 13 and 14). In order for our ASP.NET application to use these managed stored procedures, however, we need to add them to the Data Access and Business Logic Layers in the architecture. In this step we will add two new methods to the `ProductsTableAdapter` in the `NorthwindWithSprocs` Typed DataSet, which was initially created in the Creating New Stored Procedures for the Typed DataSet s TableAdapters tutorial. In Step 7 we will add corresponding methods to the BLL.

Open the `NorthwindWithSprocs` Typed DataSet in Visual Studio and start by adding a new method to the `ProductsTableAdapter` named `GetDiscontinuedProducts`. To add a new method to a TableAdapter, right-click on the TableAdapter s name in the Designer and choose the Add Query option from the context menu.

> **NOTE**
>
> Since we moved the Northwind database from the `App_Data` folder to the SQL Server 2005 Express Edition database instance, it is imperative that the corresponding connection string in Web.config be updated to reflect this change. In Step 2 we discussed updating the `NORTHWNDConnectionString` value in `Web.config`. If you forgot to make this update, then you will see the error message Failed to add query. Unable to find connection `NORTHWNDConnectionString` for object `Web.config` in a dialog box when attempting to add a new method to the TableAdapter. To resolve this error, click OK and then go to `Web.config` and update the `NORTHWNDConnectionString` value as discussed in Step 2. Then try re-adding the method to the TableAdapter. This time it should work without error.

Adding a new method launches the TableAdapter Query Configuration wizard, which we have used many times in past tutorials. The first step asks us to specify how the TableAdapter should access the database: through an ad-hoc SQL statement or via a new or existing stored procedure. Since we have already created and registered the `GetDiscontinuedProducts` managed stored procedure with the database, choose the Use existing stored procedure option and hit Next.

Figure 15: Choose the Use existing stored procedure Option (Click to view full-size image)

The next screen prompts us for the stored procedure the method will invoke. Choose the `GetDiscontinuedProducts` managed stored procedure from the drop-down list and hit Next.

Figure 16: Select the `GetDiscontinuedProducts` Managed Stored Procedure (Click to view full-size image)

We are then asked to specify whether the stored procedure returns rows, a single value, or nothing. Since `GetDiscontinuedProducts` returns the set of discontinued product rows, choose the first option (Tabular data) and click Next.

Figure 17: Select the Tabular Data Option (Click to view full-size image)

The final wizard screen allows us to specify the data access patterns used and the names of the resulting methods. Leave both checkboxes checked and name the methods `FillByDiscontinued` and `GetDiscontinuedProducts`. Click Finish to complete the wizard.

Figure 18: Name the Methods `FillByDiscontinued` and `GetDiscontinuedProducts` (Click to view full-size image)

Repeat these steps to create methods named `FillByPriceLessThan` and `GetProductsWithPriceLessThan` in the `ProductsTableAdapter` for the `GetProductsWithPriceLessThan` managed stored procedure.

Figure 19 shows a screenshot of the DataSet Designer after adding the methods to the `ProductsTableAdapter` for the `GetDiscontinuedProducts` and `GetProductsWithPriceLessThan` managed stored procedures.

Figure 19: The `ProductsTableAdapter` Includes the New Methods Added in this Step (Click to view full-size image)

Step 7: Adding Corresponding Methods to the Business Logic Layer

Now that we have updated the Data Access Layer to include methods for calling the managed stored procedures added in Steps 4 and 5, we need to add corresponding methods to the Business Logic Layer. Add the following two methods to the `ProductsBLLWithSprocs` class:

```
[System.ComponentModel.DataObjectMethodAttribute
    (System.ComponentModel.DataObjectMethodType.Select, false)]
public NorthwindWithSprocs.ProductsDataTable GetDiscontinuedProducts()
{
    return Adapter.GetDiscontinuedProducts();
}
[System.ComponentModel.DataObjectMethodAttribute
    (System.ComponentModel.DataObjectMethodType.Select, false)]
public NorthwindWithSprocs.ProductsDataTable
    GetProductsWithPriceLessThan(decimal priceLessThan)
{
    return Adapter.GetProductsWithPriceLessThan(priceLessThan);
}
```

Both methods simply call the corresponding DAL method and return the `ProductsDataTable` instance. The `DataObjectMethodAttribute` markup above each method causes these methods to be included in the drop-down list in the SELECT tab of the ObjectDataSource s Configure Data Source wizard.

Step 8: Invoking the Managed Stored Procedures from the Presentation Layer

With the Business Logic and Data Access Layers augmented to include support for calling the `GetDiscontinuedProducts` and `GetProductsWithPriceLessThan` managed stored procedures, we can now display these stored procedures results through an ASP.NET page.

Open the `ManagedFunctionsAndSprocs.aspx` page in the `AdvancedDAL` folder and, from the Toolbox, drag a GridView onto the Designer. Set the GridView s `ID` property to `DiscontinuedProducts` and, from its smart tag, bind it to a new ObjectDataSource named `DiscontinuedProductsDataSource`. Configure the ObjectDataSource to pull its data from the `ProductsBLLWithSprocs` class s `GetDiscontinuedProducts` method.

Figure 20: Configure the ObjectDataSource to Use the `ProductsBLLWithSprocs` Class (Click to view full-size image)

Figure 21: Choose the `GetDiscontinuedProducts` Method from the Drop-Down List in the SELECT Tab (Click to view full-size image)

Since this grid will be used to just display product information, set the drop-down lists in the UPDATE, INSERT, and DELETE tabs to (None) and then click Finish.

Upon completing the wizard, Visual Studio will automatically add a BoundField or CheckBoxField for each data field in the `ProductsDataTable`. Take a moment to remove all of these fields except for `ProductName` and `Discontinued`, at which point your GridView and ObjectDataSource s declarative markup should look similar to the following:

```
<asp:GridView ID="DiscontinuedProducts" runat="server"
    AutoGenerateColumns="False" DataKeyNames="ProductID"
    DataSourceID="DiscontinuedProductsDataSource">
    <Columns>
        <asp:BoundField DataField="ProductName" HeaderText="ProductName"
            SortExpression="ProductName" />
        <asp:CheckBoxField DataField="Discontinued"
            HeaderText="Discontinued"
            SortExpression="Discontinued" />
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="DiscontinuedProductsDataSource" runat="server"
    OldValuesParameterFormatString="original_{0}"
    SelectMethod="GetDiscontinuedProducts" TypeName="ProductsBLLWithSprocs">
</asp:ObjectDataSource>
```

Take a moment to view this page through a browser. When the page is visited, the ObjectDataSource calls the `ProductsBLLWithSprocs` class s `GetDiscontinuedProducts` method. As we saw in Step 7, this method calls down to the DAL s `ProductsDataTable` class s `GetDiscontinuedProducts` method, which invokes the `GetDiscontinuedProducts` stored procedure. This stored procedure is a managed stored procedure and executes the code we created in Step 3, returning the discontinued products.

The results returned by the managed stored procedure are packaged up into a `ProductsDataTable` by the DAL and then returned to the BLL, which then returns them to the Presentation Layer where they are bound to the GridView and displayed. As expected, the grid lists those products that have been discontinued.

Figure 22: The Discontinued Products are Listed (Click to view full-size image)

For further practice, add a TextBox and another GridView to the page. Have this GridView display the products less than the amount entered into the TextBox by calling the `ProductsBLLWithSprocs` class s `GetProductsWithPriceLessThan` method.

Step 9: Creating and Calling T-SQL UDFs

User-Defined Functions, or UDFs, are database objects the closely mimic the semantics of functions in programming languages. Like a function in C#, UDFs can include a variable number of input parameters and return a value of a particular type. A UDF can return either scalar data - a string, an integer, and so forth - or tabular data. Let s take a quick look at both types of UDFs, starting with a UDF that returns a scalar data type.

The following UDF calculates the estimated value of the inventory for a particular product. It does so by taking in three input parameters - the `UnitPrice`, `UnitsInStock`, and `Discontinued` values for a particular product - and returns a value of type `money`. It computes the estimated value of the inventory by multiplying the `UnitPrice` by the `UnitsInStock`. For discontinued items, this value is halved.

```
CREATE FUNCTION udf_ComputeInventoryValue
(
    @UnitPrice money,
    @UnitsInStock smallint,
    @Discontinued bit
)
RETURNS money
AS
BEGIN
    DECLARE @Value decimal
    SET @Value = ISNULL(@UnitPrice, 0) * ISNULL(@UnitsInStock, 0)
    IF @Discontinued = 1
        SET @Value = @Value * 0.5

    RETURN @Value
END
```

Once this UDF has been added to the database, it can be found through Management Studio by expanding the Programmability folder, then Functions, and then Scalar-value Functions. It can be used in a `SELECT` query like so:

```
SELECT ProductID, ProductName, dbo.udf_ComputeInventoryValue
    (UnitPrice, UnitsInStock, Discontinued) as InventoryValue
FROM Products
ORDER BY InventoryValue DESC
```

I have added the `udf_ComputeInventoryValue` UDF to the Northwind database; Figure 23 shows the output of the above `SELECT` query when viewed through Management Studio. Also note that the UDF is listed under the Scalar-value Functions folder in the Object Explorer.

Figure 23: Each Product s Inventory Values is Listed (Click to view full-size image)

UDFs can also return tabular data. For example, we can create a UDF that returns products that belong to a particular category:

```
CREATE FUNCTION dbo.udf_GetProductsByCategoryID
(
    @CategoryID int
)
RETURNS TABLE
AS
RETURN
(
    SELECT ProductID, ProductName, SupplierID, CategoryID,
           QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
           ReorderLevel, Discontinued
    FROM Products
    WHERE CategoryID = @CategoryID
)
```

The `udf_GetProductsByCategoryID` UDF accepts a `@CategoryID` input parameter and returns the results of the specified `SELECT` query. Once created, this UDF can be referenced in the `FROM` (or `JOIN`) clause of a `SELECT` query. The following example would return the `ProductID`, `ProductName`, and `CategoryID` values for each of the beverages.

```
SELECT ProductID, ProductName, CategoryID
FROM dbo.udf_GetProductsByCategoryID(1)
```

I have added the `udf_GetProductsByCategoryID` UDF to the Northwind database; Figure 24 shows the output of the above `SELECT` query when viewed through Management Studio. UDFs that return tabular data can be found in the Object Explorer s Table-value Functions folder.

Figure 24: The `ProductID`, `ProductName`, and `CategoryID` are Listed for Each Beverage (Click to view full-size image)

> **NOTE**
>
> For more information on creating and using UDFs, check out Intro to User-Defined Functions. Also check out Advantages and Drawbacks of User-Defined Functions.

Step 10: Creating a Managed UDF

The `udf_ComputeInventoryValue` and `udf_GetProductsByCategoryID` UDFs created in the above examples are T-SQL database objects. SQL Server 2005 also supports managed UDFs, which can be added to the `ManagedDatabaseConstructs` project just like the managed stored procedures from Steps 3 and 5. For this step, let s implement the `udf_ComputeInventoryValue` UDF in managed code.

To add a managed UDF to the `ManagedDatabaseConstructs` project, right-click on the project name in Solution Explorer and choose to Add a New Item. Select the User-Defined Template from the Add New Item dialog box and name the new UDF file `udf_ComputeInventoryValue_Managed.cs`.

Figure 25: Add a New Managed UDF to the `ManagedDatabaseConstructs` Project (Click to view full-size image)

The User-Defined Function template creates a `partial` class named `UserDefinedFunctions` with a method whose name is the same as the class file s name (`udf_ComputeInventoryValue_Managed` , in this instance). This method is decorated using the `SqlFunction` attribute, which flags the method as a managed UDF.

```
using System;
using System.Data;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;
public partial class UserDefinedFunctions
{
    [Microsoft.SqlServer.Server.SqlFunction]
    public static SqlString udf_ComputeInventoryValue_Managed()
    {
        // Put your code here
        return new SqlString("Hello");
    }
};
```

The `udf_ComputeInventoryValue` method currently returns a `SqlString` object and does not accept any input parameters. We need to update the method definition so that it accepts three input parameters - `UnitPrice` , `UnitsInStock` , and `Discontinued` - and returns a `SqlMoney` object. The logic for calculating the inventory value is identical to that in the T-SQL `udf_ComputeInventoryValue` UDF.

```
[Microsoft.SqlServer.Server.SqlFunction]
public static SqlMoney udf_ComputeInventoryValue_Managed
    (SqlMoney UnitPrice, SqlInt16 UnitsInStock, SqlBoolean Discontinued)
{
    SqlMoney inventoryValue = 0;
    if (!UnitPrice.IsNull && !UnitsInStock.IsNull)
    {
        inventoryValue = UnitPrice * UnitsInStock;
        if (Discontinued == true)
            inventoryValue = inventoryValue * new SqlMoney(0.5);
    }
    return inventoryValue;
}
```

Note that the UDF method s input parameters are of their corresponding SQL types: `SqlMoney` for the `UnitPrice` field, `SqlInt16` for `UnitsInStock` , and `SqlBoolean` for `Discontinued` . These data types reflect the types defined in the `Products` table: the `UnitPrice` column is of type `money` , the `UnitsInStock` column of type `smallint` , and the

`Discontinued` column of type `bit`.

The code starts by creating a `SqlMoney` instance named `inventoryValue` that is assigned a value of 0. The `Products` table allows for database `NULL` values in the `UnitsInPrice` and `UnitsInStock` columns. Therefore, we need to first check to see if these values contain `NULL` s, which we do through the `SqlMoney` object s `IsNull` property. If both `UnitPrice` and `UnitsInStock` contain non- `NULL` values, then we compute the `inventoryValue` to be the product of the two. Then, if `Discontinued` is true, then we halve the value.

> **NOTE**
> The `SqlMoney` object only allows two `SqlMoney` instances to be multiplied together. It does not allow a `SqlMoney` instance to be multiplied by a literal floating-point number. Therefore, to halve `inventoryValue` we multiply it by a new `SqlMoney` instance that has the value 0.5.

Step 11: Deploying the Managed UDF

Now that the managed UDF has been created, we are ready to deploy it to the Northwind database. As we saw in Step 4, the managed objects in a SQL Server Project are deployed by right-clicking on the project name in the Solution Explorer and choosing the Deploy option from the context menu.

Once you have deployed the project, return to SQL Server Management Studio and refresh the Scalar-valued Functions folder. You should now see two entries:

- `dbo.udf_ComputeInventoryValue` - the T-SQL UDF created in Step 9, and
- `dbo.udf ComputeInventoryValue_Managed` - the managed UDF created in Step 10 that was just deployed.

To test this managed UDF, execute the following query from within Management Studio:

```
SELECT ProductID, ProductName,
       dbo.udf_ComputeInventoryValue_Managed(
                 UnitPrice,
                 UnitsInStock,
                 Discontinued
              ) as InventoryValue
FROM Products
ORDER BY InventoryValue DESC
```

This command uses the managed `udf ComputeInventoryValue_Managed` UDF instead of the T-SQL `udf_ComputeInventoryValue` UDF, but the output is the same. Refer back to Figure 23 to see a screenshot of the UDF s output.

Step 12: Debugging the Managed Database Objects

In the Debugging Stored Procedures tutorial we discussed the three options for debugging SQL Server through Visual Studio: Direct Database Debugging, Application Debugging, and Debugging from a SQL Server Project. Managed database objects cannot be debugged via Direct Database Debugging, but can be debugged from a client application and directly from the SQL Server Project. In order for debugging to work, however, the SQL Server 2005 database must allow SQL/CLR debugging. Recall that when we first created the `ManagedDatabaseConstructs` project Visual Studio asked us whether we wanted to enable SQL/CLR debugging (see Figure 6 in Step 2). This setting can be modified by right-clicking on the database from the Server Explorer window.

Figure 26: Ensure that the Database Allows SQL/CLR Debugging

Imagine that we wanted to debug the `GetProductsWithPriceLessThan` managed stored procedure. We would start by setting a breakpoint within the code of the `GetProductsWithPriceLessThan` method.

Figure 27: Set a Breakpoint in the `GetProductsWithPriceLessThan` Method (Click to view full-size image)

Let s first look at debugging the managed database objects from the SQL Server Project. Since our Solution includes two projects - the `ManagedDatabaseConstructs` SQL Server Project along with our website - in order to debug from the SQL Server Project we need to instruct Visual Studio to launch the `ManagedDatabaseConstructs` SQL Server Project when we start debugging. Right-click the `ManagedDatabaseConstructs` project in Solution Explorer and choose the Set as StartUp Project option from the context menu.

When the `ManagedDatabaseConstructs` project is launched from the debugger it executes the SQL statements in the `Test.sql` file, which is located in the `Test Scripts` folder. For example, to test the `GetProductsWithPriceLessThan` managed stored procedure, replace the existing `Test.sql` file content with the following statement, which invokes the `GetProductsWithPriceLessThan` managed stored procedure passing in the `@CategoryID` value of 14.95:

```
exec GetProductsWithPriceLessThan 14.95
```

Once you ve entered the above script into `Test.sql`, start debugging by going to the Debug menu and choosing

Start Debugging or by hitting F5 or the green play icon in the Toolbar. This will build the projects within the Solution, deploy the managed database objects to the Northwind database, and then execute the `Test.sql` script. At this point, the breakpoint will be hit and we can step through the `GetProductsWithPriceLessThan` method, examine the values of the input parameters, and so on.

Figure 28: The Breakpoint in the `GetProductsWithPriceLessThan` Method Was Hit (Click to view full-size image)

In order for a SQL database object to be debugged through a client application, it is imperative that the database be configured to support application debugging. Right-click on the database in Server Explorer and ensure that the Application Debugging option is checked. Furthermore, we need to configure the ASP.NET application to integrate with the SQL Debugger and to disable connection pooling. These steps were discussed in detail in Step 2 of the Debugging Stored Procedures tutorial.

Once you have configured the ASP.NET application and database, set the ASP.NET website as the startup project and start debugging. If you visit a page that calls one of the managed objects that has a breakpoint, the application will halt and control will be turned over to the debugger, where you can step through the code as shown in Figure 28.

Step 13: Manually Compiling and Deploying Managed Database Objects

SQL Server Projects make it easy to create, compile, and deploy managed database objects. Unfortunately, SQL Server Projects are only available in the Professional and Team Systems editions of Visual Studio. If you are using Visual Web Developer or the Standard Edition of Visual Studio and want to use managed database objects, you will need to manually create and deploy them. This involves four steps:

1. Create a file that contains the source code for the managed database object,
2. Compile the object into an assembly,
3. Register the assembly with the SQL Server 2005 database, and
4. Create a database object in SQL Server that points to the appropriate method in the assembly.

To illustrate these tasks, let s create a new managed stored procedure that returns those products whose `UnitPrice` is greater than a specified value. Create a new file on your computer named `GetProductsWithPriceGreaterThan.cs` and enter the following code into the file (you can use Visual Studio, Notepad, or any text editor to accomplish this):

```
using System;
using System.Data;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;
public partial class StoredProcedures
{
    [Microsoft.SqlServer.Server.SqlProcedure]
    public static void GetProductsWithPriceGreaterThan(SqlMoney price)
    {
        // Create the command
        SqlCommand myCommand = new SqlCommand();
        myCommand.CommandText =
            @"SELECT ProductID, ProductName, SupplierID, CategoryID,
                     QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
                     ReorderLevel, Discontinued
              FROM Products
              WHERE UnitPrice > @MinPrice";
        myCommand.Parameters.AddWithValue("@MinPrice", price);
        // Execute the command and send back the results
        SqlContext.Pipe.ExecuteAndSend(myCommand);
    }
};
```

This code is nearly identical to that of the `GetProductsWithPriceLessThan` method created in Step 5. The only differences are the method names, the `WHERE` clause, and the parameter name used in the query. Back in the `GetProductsWithPriceLessThan` method, the `WHERE` clause read: `WHERE UnitPrice < @MaxPrice`. Here, in `GetProductsWithPriceGreaterThan`, we use: `WHERE UnitPrice > @MinPrice` .

We now need to compile this class into an assembly. From the command line, navigate to the directory where you saved the `GetProductsWithPriceGreaterThan.cs` file and use the C# compiler (`csc.exe`) to compile the class file into an assembly:

```
csc.exe /t:library /out:ManuallyCreatedDBObjects.dll GetProductsWithPriceGreaterThan.cs
```

If the folder containing `csc.exe` in not in the system s `PATH`, you will have to fully reference its path, `%WINDOWS%\Microsoft.NET\Framework\version\`, like so:

```
C:\WINDOWS\Microsoft.NET\Framework\v2.0.50727\csc.exe /t:library /out:ManuallyCreatedDBObjects.dll
GetProductsWithPriceGreaterThan.cs
```

Figure 29: Compile `GetProductsWithPriceGreaterThan.cs` Into an Assembly (Click to view full-size image)

The `/t` flag specifies that the C# class file should be compiled into a DLL (rather than an executable). The `/out`

flag specifies the name of the resulting assembly.

> **NOTE**
>
> Rather than compiling the `GetProductsWithPriceGreaterThan.cs` class file from the command line you could alternatively use Visual C# Express Edition or create a separate Class Library project in Visual Studio Standard Edition. S ren Jacob Lauritsen has kindly provided such a Visual C# Express Edition project with code for the `GetProductsWithPriceGreaterThan` stored procedure and the two managed stored procedures and UDF created in Steps 3, 5, and 10. S ren s project also includes the T-SQL commands needed to add the corresponding database objects.

With the code compiled into an assembly, we are ready to register the assembly within the SQL Server 2005 database. This can be performed through T-SQL, using the command `CREATE ASSEMBLY`, or through SQL Server Management Studio. Let s focus on using Management Studio.

From Management Studio, expand the Programmability folder in the Northwind database. One of its subfolder is Assemblies. To manually add a new Assembly to the database, right-click on the Assemblies folder and choose New Assembly from the context menu. This displays the New Assembly dialog box (see Figure 30). Click on the Browse button, select the `ManuallyCreatedDBObjects.dll` assembly we just compiled, and then click OK to add the Assembly to the database. You should not see the `ManuallyCreatedDBObjects.dll` assembly in the Object Explorer.

Figure 30: Add the `ManuallyCreatedDBObjects.dll` Assembly to the Database (Click to view full-size image)

Figure 31: The `ManuallyCreatedDBObjects.dll` is Listed in the Object Explorer

While we have added the assembly to the Northwind database, we have yet to associate a stored procedure with the `GetProductsWithPriceGreaterThan` method in the assembly. To accomplish this, open a new query window and execute the following script:

```
CREATE PROCEDURE [dbo].[GetProductsWithPriceGreaterThan]
(
    @price money
)
WITH EXECUTE AS CALLER
AS
EXTERNAL NAME [ManuallyCreatedDBObjects].[StoredProcedures].[GetProductsWithPriceGreaterThan]
GO
```

This creates a new stored procedure in the Northwind database named `GetProductsWithPriceGreaterThan` and associates it with the managed method `GetProductsWithPriceGreaterThan` (which is in the class `StoredProcedures`, which is in the assembly `ManuallyCreatedDBObjects`).

After executing the above script, refresh the Stored Procedures folder in the Object Explorer. You should see a new stored procedure entry - `GetProductsWithPriceGreaterThan` - which has a lock icon next to it. To test this stored procedure, enter and execute the following script in the query window:

```
exec GetProductsWithPriceGreaterThan 24.95
```

As Figure 32 shows, the above command displays information for those products with a `UnitPrice` greater than $24.95.

Figure 32: The `ManuallyCreatedDBObjects.dll` is Listed in the Object Explorer (Click to view full-size image)

Summary

Microsoft SQL Server 2005 provides integration with the Common Language Runtime (CLR), which allows database objects to be created using managed code. Previously, these database objects could only be created using T-SQL, but now we can create these objects using .NET programming languages like C#. In this tutorial we created two managed stored procedures and a managed User-Defined Function.

Visual Studio s SQL Server Project type facilitates creating, compiling, and deploying managed database objects. Moreover, it offers rich debugging support. However, SQL Server Project types are only available in the Professional and Team Systems editions of Visual Studio. For those using Visual Web Developer or the Standard Edition of Visual Studio, the creation, compilation, and deployment steps must be performed manually, as we saw in Step 13.

Happy Programming!

Creating New Stored Procedures for the Typed DataSet's TableAdapters (VB)

2/20/2020 • 27 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> In earlier tutorials we have created SQL statements in our code and passed the statements to the database to be executed. An alternative approach is to use stored procedures, where the SQL statements are pre-defined at the database. In this tutorial we learn how to have the TableAdapter Wizard generate new stored procedures for us.

Introduction

The Data Access Layer (DAL) for these tutorials uses Typed DataSets. As discussed in the Creating a Data Access Layer tutorial, Typed DataSets consist of strongly-typed DataTables and TableAdapters. The DataTables represent the logical entities in the system while the TableAdapters interface with the underlying database to perform the data access work. This includes populating the DataTables with data, executing queries that return scalar data, and inserting, updating, and deleting records from the database.

The SQL commands executed by the TableAdapters can be either ad-hoc SQL statements, such as `SELECT columnList FROM TableName`, or stored procedures. The TableAdapters in our architecture use ad-hoc SQL statements. Many developers and database administrators, however, prefer stored procedures over ad-hoc SQL statements for security, maintainability, and updatability reasons. Others ardently prefer ad-hoc SQL statements for their flexibility. In my own work I favor stored procedures over ad-hoc SQL statements, but chose to use ad-hoc SQL statements to simplify the earlier tutorials.

When defining a TableAdapter or adding new methods, the TableAdapter s wizard makes it just as easy to create new stored procedures or use existing stored procedures as it does to use ad-hoc SQL statements. In this tutorial we'll examine how to have the TableAdapter s wizard auto-generate stored procedures. In the next tutorial we will look at how to configure the TableAdapter s methods to use existing or manually-created stored procedures.

> **NOTE**
>
> See Rob Howard's blog entry Don t Use Stored Procedures Yet? and Frans Bouma s blog entry Stored Procedures are Bad, M Kay? for a lively debate on the pros and cons of stored procedures and ad-hoc SQL.

Stored Procedure Basics

Functions are a construct common to all programming languages. A function is a collection of statements that are executed when the function is called. Functions can accept input parameters and may optionally return a value. *Stored procedures* are database constructs that share many similarities with functions in programming languages. A stored procedure is made up of a set of T-SQL statements that are executed when the stored procedure is called. A stored procedure may accept zero to many input parameters and can return scalar values, output parameters, or, most commonly, result sets from `SELECT` queries.

> **NOTE**
> Stored procedures are oftentimes referred to as sprocs or SPs .

Stored procedures are created using the `CREATE PROCEDURE` T-SQL statement. For example, the following T-SQL script creates a stored procedure named `GetProductsByCategoryID` that takes in a single parameter named `@CategoryID` and returns the `ProductID`, `ProductName`, `UnitPrice`, and `Discontinued` fields of those columns in the `Products` table that have a matching `CategoryID` value:

```
CREATE PROCEDURE GetProductsByCategoryID
(
    @CategoryID int
)
AS
SELECT ProductID, ProductName, UnitPrice, Discontinued
FROM Products
WHERE CategoryID = @CategoryID
```

Once this stored procedure has been created, it can be called using the following syntax:

```
EXEC GetProductsByCategory categoryID
```

> **NOTE**
> In the next tutorial we will examine creating stored procedures through the Visual Studio IDE. For this tutorial, however, we are going to let the TableAdapter wizard automatically generate the stored procedures for us.

In addition to simply returning data, stored procedures are often used to perform multiple database commands within the scope of a single transaction. A stored procedure named `DeleteCategory`, for example, might take in a `@CategoryID` parameter and perform two `DELETE` statements: first, one to delete the related products and a second one deleting the specified category. Multiple statements within a stored procedure are *not* automatically wrapped within a transaction. Additional T-SQL commands need to be issued to ensure the stored procedure s multiple commands are treated as an atomic operation. We'll see how to wrap a stored procedure s commands within the scope of a transaction in the subsequent tutorial.

When using stored procedures within an architecture, the Data Access Layer s methods invoke a particular stored procedure rather than issuing an ad-hoc SQL statement. This centralizes the location of the SQL statements executed (on the database) rather than having it defined within the application s architecture. This centralization arguably makes it easier to find, analyze, and tune the queries and provides a much clearer picture as to where and how the database is being used.

For more information on stored procedure fundamentals, consult the resources in the Further Reading section at the end of this tutorial.

Step 1: Creating the Advanced Data Access Layer Scenarios Web Pages

Before we start our discussion on creating a DAL using stored procedures, let s first take a moment to create the ASP.NET pages in our website project that we will need for this and the next several tutorials. Start by adding a new folder named `AdvancedDAL`. Next, add the following ASP.NET pages to that folder, making sure to associate each page with the `Site.master` master page:

- `Default.aspx`
- `NewSprocs.aspx`
- `ExistingSprocs.aspx`
- `JOINs.aspx`
- `AddingColumns.aspx`
- `ComputedColumns.aspx`
- `EncryptingConfigSections.aspx`
- `ManagedFunctionsAndSprocs.aspx`

Figure 1: Add the ASP.NET Pages for the Advanced Data Access Layer Scenarios Tutorials

Like in the other folders, `Default.aspx` in the `AdvancedDAL` folder will list the tutorials in its section. Recall that the `SectionLevelTutorialListing.ascx` User Control provides this functionality. Therefore, add this User Control to `Default.aspx` by dragging it from the Solution Explorer onto the page s Design view.

Figure 2: Add the `SectionLevelTutorialListing.ascx` User Control to `Default.aspx` (Click to view full-size image)

Lastly, add these pages as entries to the `Web.sitemap` file. Specifically, add the following markup after the Working with Batched Data `<siteMapNode>`:

```
<siteMapNode url="~/AdvancedDAL/Default.aspx"
    title="Advanced DAL Scenarios"
    description="Explore a number of advanced Data Access Layer scenarios.">

    <siteMapNode url="~/AdvancedDAL/NewSprocs.aspx"
        title="Creating New Stored Procedures for TableAdapters"
        description="Learn how to have the TableAdapter wizard automatically
            create and use stored procedures." />
    <siteMapNode url="~/AdvancedDAL/ExistingSprocs.aspx"
        title="Using Existing Stored Procedures for TableAdapters"
        description="See how to plug existing stored procedures into a
            TableAdapter." />
    <siteMapNode url="~/AdvancedDAL/JOINs.aspx"
        title="Returning Data Using JOINs"
        description="Learn how to augment your DataTables to work with data
            returned from multiple tables via a JOIN query." />
    <siteMapNode url="~/AdvancedDAL/AddingColumns.aspx"
        title="Adding DataColumns to a DataTable"
        description="Master adding new columns to an existing DataTable." />
    <siteMapNode url="~/AdvancedDAL/ComputedColumns.aspx"
        title="Working with Computed Columns"
        description="Explore how to work with computed columns when using
            Typed DataSets." />
    <siteMapNode url="~/AdvancedDAL/EncryptingConfigSections.aspx"
        title="Protected Connection Strings in Web.config"
        description="Protect your connection string information in
            Web.config using encryption." />
    <siteMapNode url="~/AdvancedDAL/ManagedFunctionsAndSprocs.aspx"
        title="Creating Managed SQL Functions and Stored Procedures"
        description="See how to create SQL functions and stored procedures
            using managed code." />
</siteMapNode>
```

After updating `Web.sitemap`, take a moment to view the tutorials website through a browser. The menu on the left now includes items for the advanced DAL scenarios tutorials.

Figure 3: The Site Map Now Includes Entries for the Advanced DAL Scenarios Tutorials

Step 2: Configuring a TableAdapter to Create New Stored Procedures

To demonstrate creating a Data Access Layer that uses stored procedures instead of ad-hoc SQL statements, let s create a new Typed DataSet in the `~/App_Code/DAL` folder named `NorthwindWithSprocs.xsd`. Since we have stepped through this process in detail in previous tutorials, we will proceed quickly through the steps here. If you get stuck or need further step-by-step instructions in creating and configuring a Typed DataSet, refer back to the Creating a Data Access Layer tutorial.

Add a new DataSet to the project by right-clicking on the `DAL` folder, choosing Add New Item, and selecting the DataSet template as shown in Figure 4.

Figure 4: Add a New Typed DataSet to the Project Named `NorthwindWithSprocs.xsd` (Click to view full-size image)

This will create the new Typed DataSet, open its Designer, create a new TableAdapter, and launch the TableAdapter Configuration Wizard. The TableAdapter Configuration Wizard s first step asks us to select the database to work with. The connection string to the Northwind database should be listed in the drop-down list. Select this and click Next.

From this next screen we can choose how the TableAdapter should access the database. In previous tutorials, we selected the first option, Use SQL statements. For this tutorial, select the second option, Create new stored procedures, and click Next.

Figure 5: Instruct the TableAdapter to Create New Stored Procedures (Click to view full-size image)

Just like with using ad-hoc SQL statements, in the following step we are asked to provide the `SELECT` statement for the TableAdapter s main query. But instead of using the `SELECT` statement entered here to perform an ad-hoc query directly, the TableAdapter s wizard will create a stored procedure that contains this `SELECT` query.

Use the following `SELECT` query for this TableAdapter:

```
SELECT ProductID, ProductName, SupplierID, CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued
FROM Products
```

Figure 6: Enter the `SELECT` Query (Click to view full-size image)

> **NOTE**
>
> The query above differs slightly from the main query of the `ProductsTableAdapter` in the `Northwind` Typed DataSet. Recall that the `ProductsTableAdapter` in the `Northwind` Typed DataSet includes two correlated subqueries to bring back the category name and company name for each product s category and supplier. In the upcoming Updating the TableAdapter to Use JOINs tutorial we will look at adding this related data to this TableAdapter.

Take a moment to click the Advanced Options button. From here we can specify whether the wizard should also generate insert, update, and delete statements for the TableAdapter, whether to use optimistic concurrency, and whether the data table should be refreshed after inserts and updates. The Generate Insert, Update and Delete statements option is checked by default. Leave it checked. For this tutorial, leave the Use optimistic concurrency options unchecked.

When having the stored procedures automatically created by the TableAdapter wizard, it appears that the Refresh the data table option is ignored. Regardless of whether this checkbox is checked, the resulting insert and update stored procedures retrieve the just-inserted or just-updated record, as we will see in Step 3.

Figure 7: Leave the Generate Insert, Update and Delete statements Option Checked

> **NOTE**
>
> If the Use optimistic concurrency option is checked, the wizard will add additional conditions to the `WHERE` clause that prevent data from being updated if there were changes in other fields. Refer back to the Implementing Optimistic Concurrency tutorial for more information on using the TableAdapter s built-in optimistic concurrency control feature.

After entering the `SELECT` query and confirming that the Generate Insert, Update and Delete statements option is checked, click Next. This next screen, shown in Figure 8, prompts for the names of the stored procedures the wizard will create for selecting, inserting, updating, and deleting data. Change these stored procedures names to `Products_Select`, `Products_Insert`, `Products_Update`, and `Products_Delete`.

Figure 8: Rename the Stored Procedures (Click to view full-size image)

To see the T-SQL the TableAdapter wizard will use to create the four stored procedures, click the Preview SQL Script button. From the Preview SQL Script dialog box you may save the script to a file or copy it to the clipboard.

Figure 9: Preview the SQL Script Used to Generate the Stored Procedures

After naming the stored procedures, click Next to name the TableAdapter s corresponding methods. Just like when using ad-hoc SQL statements, we can create methods that fill an existing DataTable or return a new one. We can also specify whether the TableAdapter should include the DB-Direct pattern for inserting, updating, and deleting records. Leave all three checkboxes checked, but rename the Return a DataTable method to `GetProducts` (as shown in Figure 10).

Figure 10: Name the Methods `Fill` and `GetProducts` (Click to view full-size image)

Click Next to see a summary of the steps the wizard will perform. Complete the wizard by clicking the Finish button. Once the wizard completes, you will be returned to the DataSet s Designer, which should now include the `ProductsDataTable`.

Figure 11: The DataSet s Designer Shows the Newly Added `ProductsDataTable` (Click to view full-size image)

Step 3: Examining the Newly Created Stored Procedures

The TableAdapter wizard used in Step 2 automatically created the stored procedures for selecting, inserting, updating, and deleting data. These stored procedures can be viewed or modified through Visual Studio by going to the Server Explorer and drilling down into the database s Stored Procedures folder. As Figure 12 shows, the Northwind database contains four new stored procedures: `Products_Delete`, `Products_Insert`, `Products_Select`, and `Products_Update`.

Figure 12: The Four Stored Procedures Created in Step 2 Can Be Found in the Database s Stored Procedures Folder

> **NOTE**
>
> If you do not see the Server Explorer, go to the View menu and choose the Server Explorer option. If you do not see the product-related stored procedures added from Step 2, try right-clicking on the Stored Procedures folder and choosing Refresh.

To view or modify a stored procedure, double-click its name in the Server Explorer or, alternatively, right-click on the stored procedure and choose Open. Figure 13 shows the `Products_Delete` stored procedure, when opened.

Figure 13: Stored Procedures Can Be Opened and Modified From Within Visual Studio (Click to view full-size image)

The contents of both the `Products_Delete` and `Products_Select` stored procedures are quite straightforward. The `Products_Insert` and `Products_Update` stored procedures, on the other hand, warrant a closer inspection as they

both perform a `SELECT` statement after their `INSERT` and `UPDATE` statements. For example, the following SQL makes up the `Products_Insert` stored procedure:

```
ALTER PROCEDURE dbo.Products_Insert
(
    @ProductName nvarchar(40),
    @SupplierID int,
    @CategoryID int,
    @QuantityPerUnit nvarchar(20),
    @UnitPrice money,
    @UnitsInStock smallint,
    @UnitsOnOrder smallint,
    @ReorderLevel smallint,
    @Discontinued bit
)
AS
    SET NOCOUNT OFF;
INSERT INTO [Products] ([ProductName], [SupplierID], [CategoryID], [QuantityPerUnit],
    [UnitPrice], [UnitsInStock], [UnitsOnOrder], [ReorderLevel], [Discontinued])
VALUES (@ProductName, @SupplierID, @CategoryID, @QuantityPerUnit, @UnitPrice,
    @UnitsInStock, @UnitsOnOrder, @ReorderLevel, @Discontinued);

SELECT ProductID, ProductName, SupplierID, CategoryID, QuantityPerUnit, UnitPrice,
    UnitsInStock, UnitsOnOrder, ReorderLevel, Discontinued
FROM Products
WHERE (ProductID = SCOPE_IDENTITY())
```

The stored procedure accepts as input parameters the `Products` columns that were returned by the `SELECT` query specified in the TableAdapter s wizard and these values are used in an `INSERT` statement. Following the `INSERT` statement, a `SELECT` query is used to return the `Products` column values (including the `ProductID`) of the newly added record. This refresh capability is useful when adding a new record using the Batch Update pattern as it automatically updates the newly added `ProductRow` instances `ProductID` properties with the auto-incremented values assigned by the database.

The following code illustrates this feature. It contains a `ProductsTableAdapter` and `ProductsDataTable` created for the `NorthwindWithSprocs` Typed DataSet. A new product is added to the database by creating a `ProductsRow` instance, supplying its values, and calling the TableAdapter s `Update` method, passing in the `ProductsDataTable`. Internally, the TableAdapter s `Update` method enumerates the `ProductsRow` instances in the passed-in DataTable (in this example there is only one - the one we just added), and performs the appropriate insert, update, or delete command. In this case, the `Products_Insert` stored procedure is executed, which adds a new record to the `Products` table and returns the details of the newly-added record. The `ProductsRow` instance s `ProductID` value is then updated. After the `Update` method has completed, we can access the newly-added record s `ProductID` value through the `ProductsRow` s `ProductID` property.

```
' Create the ProductsTableAdapter and ProductsDataTable
Dim productsAPI As New NorthwindWithSprocsTableAdapters.ProductsTableAdapter
Dim products As New NorthwindWithSprocs.ProductsDataTable
' Create a new ProductsRow instance and set its properties
Dim product As NorthwindWithSprocs.ProductsRow = products.NewProductsRow()
product.ProductName = "New Product"
product.CategoryID = 1  ' Beverages
product.Discontinued = False
' Add the ProductsRow instance to the DataTable
products.AddProductsRow(product)
' Update the DataTable using the Batch Update pattern
productsAPI.Update(products)
' At this point, we can determine the value of the newly-added record's ProductID
Dim newlyAddedProductIDValue as Integer = product.ProductID
```

The `Products_Update` stored procedure similarly includes a `SELECT` statement after its `UPDATE` statement.

```
ALTER PROCEDURE dbo.Products_Update
(
    @ProductName nvarchar(40),
    @SupplierID int,
    @CategoryID int,
    @QuantityPerUnit nvarchar(20),
    @UnitPrice money,
    @UnitsInStock smallint,
    @UnitsOnOrder smallint,
    @ReorderLevel smallint,
    @Discontinued bit,
    @Original_ProductID int,
    @ProductID int
)
AS
    SET NOCOUNT OFF;
UPDATE [Products]
SET [ProductName] = @ProductName, [SupplierID] = @SupplierID,
    [CategoryID] = @CategoryID, [QuantityPerUnit] = @QuantityPerUnit,
    [UnitPrice] = @UnitPrice, [UnitsInStock] = @UnitsInStock,
    [UnitsOnOrder] = @UnitsOnOrder, [ReorderLevel] = @ReorderLevel,
    [Discontinued] = @Discontinued
WHERE (([ProductID] = @Original_ProductID));

SELECT ProductID, ProductName, SupplierID, CategoryID, QuantityPerUnit,
    UnitPrice, UnitsInStock, UnitsOnOrder, ReorderLevel, Discontinued
FROM Products
WHERE (ProductID = @ProductID)
```

Note that this stored procedure includes two input parameters for `ProductID`: `@Original_ProductID` and `@ProductID`. This functionality allows for scenarios where the primary key might be changed. For example, in an employee database, each employee record might use the employee s social security number as their primary key. In order to change an existing employee s social security number, both the new social security number and the original one must be supplied. For the `Products` table, such functionality is not needed because the `ProductID` column is an `IDENTITY` column and should never be changed. In fact, the `UPDATE` statement in the `Products_Update` stored procedure doesn t include the `ProductID` column in its column list. So, while `@Original_ProductID` is used in the `UPDATE` statement s `WHERE` clause, it is superfluous for the `Products` table and could be replaced by the `@ProductID` parameter. When modifying a stored procedure s parameters it is important that the TableAdapter method(s) that use that stored procedure are also updated.

Step 4: Modifying a Stored Procedure s Parameters and Updating the TableAdapter

Since the `@Original_ProductID` parameter is superfluous, let s remove it from the `Products_Update` stored procedure altogether. Open the `Products_Update` stored procedure, delete the `@Original_ProductID` parameter, and, in the `WHERE` clause of the `UPDATE` statement, change the parameter name used from `@Original_ProductID` to `@ProductID`. After making these changes, the T-SQL within the stored procedure should look like the following:

```
ALTER PROCEDURE dbo.Products_Update
(
    @ProductName nvarchar(40),
    @SupplierID int,
    @CategoryID int,
    @QuantityPerUnit nvarchar(20),
    @UnitPrice money,
    @UnitsInStock smallint,
    @UnitsOnOrder smallint,
    @ReorderLevel smallint,
    @Discontinued bit,
    @ProductID int
)
AS
    SET NOCOUNT OFF;
UPDATE [Products] SET [ProductName] = @ProductName, [SupplierID] = @SupplierID,
    [CategoryID] = @CategoryID, [QuantityPerUnit] = @QuantityPerUnit,
    [UnitPrice] = @UnitPrice, [UnitsInStock] = @UnitsInStock,
    [UnitsOnOrder] = @UnitsOnOrder, [ReorderLevel] = @ReorderLevel,
    [Discontinued] = @Discontinued
WHERE (([ProductID] = @ProductID));

SELECT ProductID, ProductName, SupplierID, CategoryID, QuantityPerUnit,
    UnitPrice, UnitsInStock, UnitsOnOrder, ReorderLevel, Discontinued
FROM Products
WHERE (ProductID = @ProductID)
```

To save these changes to the database, click the Save icon in the toolbar or hit Ctrl+S. At this point, the `Products_Update` stored procedure does not expect an `@Original_ProductID` input parameter, but the TableAdapter is configured to pass such a parameter. You can see the parameters the TableAdapter will send to the `Products_Update` stored procedure by selecting the TableAdapter in the DataSet Designer, going to the Properties window, and clicking the ellipses in the `UpdateCommand` s `Parameters` collection. This brings up the Parameters Collection Editor dialog box shown in Figure 14.

Figure 14: The Parameters Collection Editor Lists the Parameters Used Passed to the `Products_Update` Stored Procedure

You can remove this parameter from here by simply selecting the `@Original_ProductID` parameter from the list of members and clicking the Remove button.

Alternatively, you can refresh the parameters used for all of the methods by right-clicking on the TableAdapter in the Designer and choosing Configure. This will bring up the TableAdapter Configuration wizard, listing the stored procedures used for selecting, inserting, updating, and deleting, along with the parameters the stored procedures

expect to receive. If you click on the Update drop-down list you can see the `Products_Update` stored procedures expected input parameters, which now no longer includes `@Original_ProductID` (see Figure 15). Simply click Finish to automatically update the parameter collection used by the TableAdapter.

Figure 15: You Can Alternatively Use the TableAdapter s Configuration Wizard to Refresh Its Methods Parameter Collections (Click to view full-size image)

Step 5: Adding Additional TableAdapter Methods

As Step 2 illustrated, when creating a new TableAdapter it is easy to have the corresponding stored procedures automatically generated. The same is true when adding additional methods to a TableAdapter. To illustrate this, let s add a `GetProductByProductID(productID)` method to the `ProductsTableAdapter` created in Step 2. This method will take as input a `ProductID` value and return details about the specified product.

Start by right-clicking on the TableAdapter and choosing Add Query from the context menu.

Figure 16: Add a New Query to the TableAdapter

This will start the TableAdapter Query Configuration wizard, which first prompts for how the TableAdapter should access the database. To have a new stored procedure created, choose the Create a new stored procedure option and click Next.

Figure 17: Choose the Create a new stored procedure Option (Click to view full-size image)

The next screen asks us to identify the type of query to execute, whether it will return a set of rows or a single scalar value, or perform an `UPDATE`, `INSERT`, or `DELETE` statement. Since the `GetProductByProductID(productID)` method will return a row, leave the SELECT which returns row option selected and hit Next.

Figure 18: Choose the SELECT which returns row Option (Click to view full-size image)

The next screen displays the TableAdapter s main query, which just lists the name of the stored procedure (`dbo.Products_Select`). Replace the stored procedure name with the following `SELECT` statement, which returns all of the product fields for a specified product:

```
SELECT ProductID, ProductName, SupplierID, CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued
FROM Products
WHERE ProductID = @ProductID
```

Figure 19: Replace the Stored Procedure Name with a `SELECT` Query (Click to view full-size image)

The subsequent screen asks you to name the stored procedure that will be created. Enter the name `Products_SelectByProductID` and click Next.

Figure 20: Name the New Stored Procedure `Products_SelectByProductID` (Click to view full-size image)

The final step of the wizard allows us to change the method names generated as well as indicate whether to use the Fill a DataTable pattern, Return a DataTable pattern, or both. For this method, leave both options checked, but rename the methods to `FillByProductID` and `GetProductByProductID`. Click Next to view a summary of the steps the wizard will perform and then click Finish to complete the wizard.

Figure 21: Rename the TableAdapter s Methods to `FillByProductID` and `GetProductByProductID` (Click to view full-size image)

After completing the wizard, the TableAdapter has a new method available, `GetProductByProductID(productID)` that, when invoked, will execute the `Products_SelectByProductID` stored procedure that was just created. Take a moment to view this new stored procedure from the Server Explorer by drilling into the Stored Procedures folder and opening `Products_SelectByProductID` (if you do not see it, right-click on the Stored Procedures folder and

choose Refresh).

Note that the `SelectByProductID` stored procedure takes `@ProductID` as an input parameter and executes the `SELECT` statement that we entered in the wizard.

```
ALTER PROCEDURE dbo.Products_SelectByProductID
(
    @ProductID int
)
AS
    SET NOCOUNT ON;
SELECT ProductID, ProductName, SupplierID, CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued
FROM Products
WHERE ProductID = @ProductID
```

Step 6: Creating a Business Logic Layer Class

Throughout the tutorial series we have strived to maintain a layered architecture in which the Presentation Layer made all of its calls to the Business Logic Layer (BLL). In order to adhere to this design decision, we first need to create a BLL class for the new Typed DataSet before we can access product data from the Presentation Layer.

Create a new class file named `ProductsBLLWithSprocs.vb` in the `~/App_Code/BLL` folder and add to it the following code:

```
Imports NorthwindWithSprocsTableAdapters
<System.ComponentModel.DataObject()> _
Public Class ProductsBLLWithSprocs
    Private _productsAdapter As ProductsTableAdapter = Nothing
    Protected ReadOnly Property Adapter() As ProductsTableAdapter
        Get
            If _productsAdapter Is Nothing Then
                _productsAdapter = New ProductsTableAdapter()
            End If
            Return _productsAdapter
        End Get
    End Property
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Select, True)> _
    Public Function GetProducts() As NorthwindWithSprocs.ProductsDataTable
        Return Adapter.GetProducts()
    End Function
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Select, False)> _
    Public Function GetProductByProductID(ByVal productID As Integer) _
        As NorthwindWithSprocs.ProductsDataTable
        Return Adapter.GetProductByProductID(productID)
    End Function
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Insert, True)> _
    Public Function AddProduct _
        (ByVal productName As String, ByVal supplierID As Nullable(Of Integer), _
         ByVal categoryID As Nullable(Of Integer), ByVal quantityPerUnit As String, _
         ByVal unitPrice As Nullable(Of Decimal), _
         ByVal unitsInStock As Nullable(Of Short), _
         ByVal unitsOnOrder As Nullable(Of Short), _
         ByVal reorderLevel As Nullable(Of Short), _
         ByVal discontinued As Boolean) _
         As Boolean

        ' Create a new ProductRow instance
        Dim products As New NorthwindWithSprocs.ProductsDataTable()
        Dim product As NorthwindWithSprocs.ProductsRow = products.NewProductsRow()
```

```
        Dim product As NorthwindWithSprocs.ProductsRow = products.NewProductsRow()
        product.ProductName = productName
        If Not supplierID.HasValue Then
            product.SetSupplierIDNull()
        Else
            product.SupplierID = supplierID.Value
        End If
        If Not categoryID.HasValue Then
            product.SetCategoryIDNull()
        Else
            product.CategoryID = categoryID.Value
        End If
        If quantityPerUnit Is Nothing Then
            product.SetQuantityPerUnitNull()
        Else
            product.QuantityPerUnit = quantityPerUnit
        End If
        If Not unitPrice.HasValue Then
            product.SetUnitPriceNull()
        Else
            product.UnitPrice = unitPrice.Value
        End If
        If Not unitsInStock.HasValue Then
            product.SetUnitsInStockNull()
        Else
            product.UnitsInStock = unitsInStock.Value
        End If
        If Not unitsOnOrder.HasValue Then
            product.SetUnitsOnOrderNull()
        Else
            product.UnitsOnOrder = unitsOnOrder.Value
        End If
        If Not reorderLevel.HasValue Then
            product.SetReorderLevelNull()
        Else
            product.ReorderLevel = reorderLevel.Value
        End If
        product.Discontinued = discontinued
        ' Add the new product
        products.AddProductsRow(product)
        Dim rowsAffected As Integer = Adapter.Update(products)
        ' Return true if precisely one row was inserted, otherwise false
        Return rowsAffected = 1
    End Function
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Update, True)> _
    Public Function UpdateProduct
        (ByVal productName As String, ByVal supplierID As Nullable(Of Integer), _
         ByVal categoryID As Nullable(Of Integer), ByVal quantityPerUnit As String, _
         ByVal unitPrice As Nullable(Of Decimal), _
         ByVal unitsInStock As Nullable(Of Short), _
         ByVal unitsOnOrder As Nullable(Of Short), _
         ByVal reorderLevel As Nullable(Of Short), _
         ByVal discontinued As Boolean, ByVal productID As Integer) _
         As Boolean

        Dim products As NorthwindWithSprocs.ProductsDataTable = _
            Adapter.GetProductByProductID(productID)
        If products.Count = 0 Then
            ' no matching record found, return false
            Return False
        End If
        Dim product As NorthwindWithSprocs.ProductsRow = products(0)
        product.ProductName = productName
        If Not supplierID.HasValue Then
            product.SetSupplierIDNull()
        Else
            product.SupplierID = supplierID.Value
        End If
```

```
        If Not categoryID.HasValue Then
            product.SetCategoryIDNull()
        Else
            product.CategoryID = categoryID.Value
        End If
        If quantityPerUnit Is Nothing Then
            product.SetQuantityPerUnitNull()
        Else
            product.QuantityPerUnit = quantityPerUnit
        End If
        If Not unitPrice.HasValue Then
            product.SetUnitPriceNull()
        Else
            product.UnitPrice = unitPrice.Value
        End If
        If Not unitsInStock.HasValue Then
            product.SetUnitsInStockNull()
        Else
            product.UnitsInStock = unitsInStock.Value
        End If
        If Not unitsOnOrder.HasValue Then
            product.SetUnitsOnOrderNull()
        Else
            product.UnitsOnOrder = unitsOnOrder.Value
        End If
        If Not reorderLevel.HasValue Then
            product.SetReorderLevelNull()
        Else
            product.ReorderLevel = reorderLevel.Value
        End If
        product.Discontinued = discontinued
        ' Update the product record
        Dim rowsAffected As Integer = Adapter.Update(product)
        ' Return true if precisely one row was updated, otherwise false
        Return rowsAffected = 1
    End Function
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Delete, True)> _
    Public Function DeleteProduct(ByVal productID As Integer) As Boolean
        Dim rowsAffected As Integer = Adapter.Delete(productID)
        ' Return true if precisely one row was deleted, otherwise false
        Return rowsAffected = 1
    End Function
End Class
```

This class mimics the `ProductsBLL` class semantics from earlier tutorials, but uses the `ProductsTableAdapter` and `ProductsDataTable` objects from the `NorthwindWithSprocs` DataSet. For example, rather than having a `Imports NorthwindTableAdapters` statement at the start of the class file as `ProductsBLL` does, the `ProductsBLLWithSprocs` class uses `Imports NorthwindWithSprocsTableAdapters`. Likewise, the `ProductsDataTable` and `ProductsRow` objects used in this class are prefixed with the `NorthwindWithSprocs` namespace. The `ProductsBLLWithSprocs` class provides two data access methods, `GetProducts` and `GetProductByProductID`, and methods to add, update, and delete a single product instance.

Step 7: Working with the `NorthwindWithSprocs` DataSet from the Presentation Layer

At this point we have created a DAL that uses stored procedures to access and modify the underlying database data. We have also built a rudimentary BLL with methods to retrieve all products or a particular product along with methods for adding, updating, and deleting products. To round off this tutorial, let s create an ASP.NET page that uses the BLL s `ProductsBLLWithSprocs` class for displaying, updating, and deleting records.

Open the `NewSprocs.aspx` page in the `AdvancedDAL` folder and drag a GridView from the Toolbox onto the

Designer, naming it `Products`. From the GridView s smart tag choose to bind it to a new ObjectDataSource named `ProductsDataSource`. Configure the ObjectDataSource to use the `ProductsBLLWithSprocs` class, as shown in Figure 22.

Figure 22: Configure the ObjectDataSource to Use the `ProductsBLLWithSprocs` Class (Click to view full-size image)

The drop-down list in the SELECT tab has two options, `GetProducts` and `GetProductByProductID`. Since we want to display all products in the GridView, choose the `GetProducts` method. The drop-down lists in the UPDATE, INSERT, and DELETE tabs each only have one method. Ensure that each of these drop-down lists has its appropriate method selected and then click Finish.

After the ObjectDataSource wizard has completed, Visual Studio will add BoundFields and a CheckBoxField to the GridView for the product data fields. Turn on the GridView s built-in editing and deleting features by checking the Enable Editing and Enable Deleting options present in the smart tag.

Figure 23: The Page Contains a GridView with Editing and Deleting Support Enabled (Click to view full-size image)

As we ve discussed in previous tutorials, at the completion of the ObjectDataSource s wizard, Visual Studio sets the `OldValuesParameterFormatString` property to original_{0}. This needs to be reverted to its default value of {0} in order for the data modification features to work properly given the parameters expected by the methods in our BLL. Therefore, be sure to set the `OldValuesParameterFormatString` property to {0} or remove the property altogether from the declarative syntax.

After completing the Configure Data Source wizard, turning on editing and deleting support in the GridView, and returning the ObjectDataSource s `OldValuesParameterFormatString` property to its default value, your page s declarative markup should look similar to the following:

```
<asp:GridView ID="Products" runat="server" AutoGenerateColumns="False"
    DataKeyNames="ProductID" DataSourceID="ProductsDataSource">
    <Columns>
        <asp:CommandField ShowDeleteButton="True" ShowEditButton="True" />
        <asp:BoundField DataField="ProductID" HeaderText="ProductID"
            InsertVisible="False" ReadOnly="True"
            SortExpression="ProductID" />
        <asp:BoundField DataField="ProductName" HeaderText="ProductName"
            SortExpression="ProductName" />
        <asp:BoundField DataField="SupplierID" HeaderText="SupplierID"
            SortExpression="SupplierID" />
        <asp:BoundField DataField="CategoryID" HeaderText="CategoryID"
            SortExpression="CategoryID" />
        <asp:BoundField DataField="QuantityPerUnit" HeaderText="QuantityPerUnit"
            SortExpression="QuantityPerUnit" />
        <asp:BoundField DataField="UnitPrice" HeaderText="UnitPrice"
            SortExpression="UnitPrice" />
        <asp:BoundField DataField="UnitsInStock" HeaderText="UnitsInStock"
            SortExpression="UnitsInStock" />
        <asp:BoundField DataField="UnitsOnOrder" HeaderText="UnitsOnOrder"
            SortExpression="UnitsOnOrder" />
        <asp:BoundField DataField="ReorderLevel" HeaderText="ReorderLevel"
            SortExpression="ReorderLevel" />
        <asp:CheckBoxField DataField="Discontinued" HeaderText="Discontinued"
            SortExpression="Discontinued" />
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="ProductsDataSource" runat="server"
    DeleteMethod="DeleteProduct" InsertMethod="AddProduct"
    SelectMethod="GetProducts" TypeName="ProductsBLLWithSprocs"
    UpdateMethod="UpdateProduct">
    <DeleteParameters>
        <asp:Parameter Name="productID" Type="Int32" />
    </DeleteParameters>
    <UpdateParameters>
        <asp:Parameter Name="productName" Type="String" />
        <asp:Parameter Name="supplierID" Type="Int32" />
        <asp:Parameter Name="categoryID" Type="Int32" />
        <asp:Parameter Name="quantityPerUnit" Type="String" />
        <asp:Parameter Name="unitPrice" Type="Decimal" />
        <asp:Parameter Name="unitsInStock" Type="Int16" />
        <asp:Parameter Name="unitsOnOrder" Type="Int16" />
        <asp:Parameter Name="reorderLevel" Type="Int16" />
        <asp:Parameter Name="discontinued" Type="Boolean" />
        <asp:Parameter Name="productID" Type="Int32" />
    </UpdateParameters>
    <InsertParameters>
        <asp:Parameter Name="productName" Type="String" />
        <asp:Parameter Name="supplierID" Type="Int32" />
        <asp:Parameter Name="categoryID" Type="Int32" />
        <asp:Parameter Name="quantityPerUnit" Type="String" />
        <asp:Parameter Name="unitPrice" Type="Decimal" />
        <asp:Parameter Name="unitsInStock" Type="Int16" />
        <asp:Parameter Name="unitsOnOrder" Type="Int16" />
        <asp:Parameter Name="reorderLevel" Type="Int16" />
        <asp:Parameter Name="discontinued" Type="Boolean" />
    </InsertParameters>
</asp:ObjectDataSource>
```

At this point we could tidy up the GridView by customizing the editing interface to include validation, having the `CategoryID` and `SupplierID` columns render as DropDownLists, and so on. We could also add a client-side confirmation to the Delete button, and I encourage you to take the time to implement these enhancements. Since these topics have been covered in previous tutorials, however, we will not cover them again here.

Regardless of whether you enhance the GridView or not, test out the page s core features in a browser. As Figure

24 shows, the page lists the products in a GridView that provides per-row editing and deleting capabilities.

Figure 24: The Products Can Be Viewed, Edited, and Deleted from the GridView (Click to view full-size image)

Summary

The TableAdapters in a Typed DataSet can access data from the database using ad-hoc SQL statements or through stored procedures. When working with stored procedures, either existing stored procedures can be used or the TableAdapter wizard can be instructed to create new stored procedures based on a `SELECT` query. In this tutorial we explored how to have the stored procedures automatically created for us.

While having the stored procedures auto-generated helps save time, there are certain cases where the stored procedure created by the wizard doesn t align with what we would have created on our own. One example is the `Products_Update` stored procedure, which expected both `@Original_ProductID` and `@ProductID` input parameters even though the `@Original_ProductID` parameter was superfluous.

In many scenarios, the stored procedures may already have been created, or we may want to build them manually so as to have a finer degree of control over the stored procedure s commands. In either case, we would want to instruct the TableAdapter to use existing stored procedures for its methods. We shall see how to accomplish this in the next tutorial.

Happy Programming!

Using Existing Stored Procedures for the Typed DataSet's TableAdapters (VB)

2/20/2020 • 17 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> In the previous tutorial we learned how to use the TableAdapter Wizard to generate new stored procedures. In this tutorial we learn how the same TableAdapter Wizard can work with existing stored procedures. We also learn how to manually add new stored procedures to our database.

Introduction

In the preceding tutorial we saw how the Typed DataSet s TableAdapters could be configured to use stored procedures to access data rather than ad-hoc SQL statements. In particular, we examined how to have the TableAdapter wizard automatically create these stored procedures. When porting a legacy application to ASP.NET 2.0 or when building an ASP.NET 2.0 website around an existing data model, chances are that the database already contains the stored procedures we need. Alternatively, you may prefer to create your stored procedures by hand or through some tool other than the TableAdapter wizard that auto-generates your stored procedures.

In this tutorial we will look at how to configure the TableAdapter to use existing stored procedures. Since the Northwind database only has a small set of built-in stored procedures, we will also look at the steps needed to manually add new stored procedures to the database through the Visual Studio environment. Let s get started!

> **NOTE**
>
> In the Wrapping Database Modifications within a Transaction tutorial we added methods to the TableAdapter to support transactions (`BeginTransaction` , `CommitTransaction` , and so on). Alternatively, transactions can be managed entirely within a stored procedure, which requires no modifications to the Data Access Layer code. In this tutorial we'll explore the T-SQL commands used to execute a stored procedure s statements within the scope of a transaction.

Step 1: Adding Stored Procedures to the Northwind Database

Visual Studio makes it easy to add new stored procedures to a database. Let s add a new stored procedure to the Northwind database that returns all columns from the `Products` table for those that have a particular `CategoryID` value. From the Server Explorer window, expand the Northwind database so that its folders - Database Diagrams, Tables, Views, and so forth - are displayed. As we saw in the preceding tutorial, the Stored Procedures folder contains the database s existing stored procedures. To add a new stored procedure, simply right-click the Stored Procedures folder and choose the Add New Stored Procedure option from the context menu.

Figure 1: Right-Click the Stored Procedures Folder and Add a New Stored Procedure (Click to view full-size image)

As Figure 1 shows, selecting the Add New Stored Procedure option opens a script window in Visual Studio with the outline of the SQL script needed to create the stored procedure. It is our job to flesh out this script and execute it, at which point the stored procedure will be added to the database.

Enter the following script:

```
CREATE PROCEDURE dbo.Products_SelectByCategoryID
(
    @CategoryID int
)
AS
SELECT ProductID, ProductName, SupplierID, CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued
FROM Products
WHERE CategoryID = @CategoryID
```

This script, when executed, will add a new stored procedure to the Northwind database named `Products_SelectByCategoryID`. This stored procedure accepts a single input parameter (`@CategoryID`, of type `int`) and it returns all of the fields for those products with a matching `CategoryID` value.

To execute this `CREATE PROCEDURE` script and add the stored procedure to the database, click the Save icon in the toolbar or hit Ctrl+S. After doing so, the Stored Procedures folder refreshes, showing the newly created stored procedure. Also, the script in the window will change subtlety from `CREATE PROCEDURE dbo.Products_SelectProductByCategoryID` to `ALTER PROCEDURE dbo.Products_SelectProductByCategoryID`. `CREATE PROCEDURE` adds a new stored procedure to the database, while `ALTER PROCEDURE` updates an existing one. Since the start of the script has changed to `ALTER PROCEDURE`, changing the stored procedures input parameters or SQL statements and clicking the Save icon will update the stored procedure with these changes.

Figure 2 shows Visual Studio after the `Products_SelectByCategoryID` stored procedure has been saved.

Figure 2: The Stored Procedure `Products_SelectByCategoryID` Has Been Added to the Database (Click to view full-size image)

Step 2: Configuring the TableAdapter to Use an Existing Stored Procedure

Now that the `Products_SelectByCategoryID` stored procedure has been added to the database, we can configure our Data Access Layer to use this stored procedure when one of its methods is invoked. In particular, we will add a `GetProductsByCategoryID(<_i22_>categoryID)<!--_i22_-->` method to the `ProductsTableAdapter` in the `NorthwindWithSprocs` Typed DataSet that calls the `Products_SelectByCategoryID` stored procedure we just created.

Start by opening the `NorthwindWithSprocs` DataSet. Right-click on the `ProductsTableAdapter` and choose Add Query to launch the TableAdapter Query Configuration wizard. In the preceding tutorial we opted to have the TableAdapter create a new stored procedure for us. For this tutorial, however, we want to wire the new TableAdapter method to the existing `Products_SelectByCategoryID` stored procedure. Therefore, choose the Use existing stored procedure option from the wizard s first step and then click Next.

Figure 3: Choose the Use existing stored procedure Option (Click to view full-size image)

The following screen provides a drop-down list populated with the database s stored procedures. Selecting a stored procedure lists its input parameters on the left and the data fields returned (if any) on the right. Choose the `Products_SelectByCategoryID` stored procedure from the list and click Next.

Figure 4: Pick the `Products_SelectByCategoryID` Stored Procedure (Click to view full-size image)

The next screen asks us what kind of data is returned by the stored procedure and our answer here determines the type returned by the TableAdapter s method. For example, if we indicate that tabular data is returned, the method will return a `ProductsDataTable` instance populated with the records returned by the stored procedure. In contrast, if we indicate that this stored procedure returns a single value the TableAdapter will return an `Object` that is assigned the value in the first column of the first record returned by the stored procedure.

Since the `Products_SelectByCategoryID` stored procedure returns all products that belong to a particular category, choose the first answer - Tabular data - and click Next.

Figure 5: Indicate that the Stored Procedure Returns Tabular Data (Click to view full-size image)

All that remains is to indicate what method patterns to use followed by the names for these methods. Leave both the Fill a DataTable and Return a DataTable options checked, but rename the methods to `FillByCategoryID` and `GetProductsByCategoryID`. Then click Next to review a summary of the tasks the wizard will perform. If everything looks correct, click Finish.

Figure 6: Name the Methods `FillByCategoryID` and `GetProductsByCategoryID` (Click to view full-size image)

> **NOTE**
>
> The TableAdapter methods we just created, `FillByCategoryID` and `GetProductsByCategoryID`, expect an input parameter of type `Integer`. This input parameter value is passed into the stored procedure via its `@CategoryID` parameter. If you modify the `Products_SelectByCategory` stored procedure s parameters, you'll need to also update the parameters for these TableAdapter methods. As discussed in the previous tutorial, this can be done in one of two ways: by manually adding or removing parameters from the parameters collection or by rerunning the TableAdapter wizard.

Step 3: Adding a `GetProductsByCategoryID(categoryID)` Method to the BLL

With the `GetProductsByCategoryID` DAL method complete, the next step is to provide access to this method in the Business Logic Layer. Open the `ProductsBLLWithSprocs` class file and add the following method:

```
<System.ComponentModel.DataObjectMethodAttribute _
    (System.ComponentModel.DataObjectMethodType.Select, False)> _
Public Function GetProductsByCategoryID(ByVal categoryID As Integer) _
    As NorthwindWithSprocs.ProductsDataTable
    Return Adapter.GetProductsByCategoryID(categoryID)
End Function
```

This BLL method simply returns the `ProductsDataTable` returned from the `ProductsTableAdapter` s `GetProductsByCategoryID` method. The `DataObjectMethodAttribute` attribute provides metadata used by the ObjectDataSource s Configure Data Source wizard. In particular, this method will appear in the SELECT tab s drop-down list.

Step 4: Displaying Products by Category

To test the newly added `Products_SelectByCategoryID` stored procedure and the corresponding DAL and BLL

methods, let s create an ASP.NET page that contains a DropDownList and a GridView. The DropDownList will list all of the categories in the database while the GridView will display the products belonging to the selected category.

> **NOTE**
>
> We ve created master/detail interfaces using DropDownLists in previous tutorials. For a more in-depth look at implementing such a master/detail report, refer to the Master/Detail Filtering With a DropDownList tutorial.

Open the `ExistingSprocs.aspx` page in the `AdvancedDAL` folder and drag a DropDownList from the Toolbox onto the Designer. Set the DropDownList s `ID` property to `Categories` and its `AutoPostBack` property to `True`. Next, from its smart tag, bind the DropDownList to a new ObjectDataSource named `CategoriesDataSource`. Configure the ObjectDataSource so that it retrieves its data from the `CategoriesBLL` class s `GetCategories` method. Set the drop-down lists in the UPDATE, INSERT, and DELETE tabs to (None) .

Figure 7: Retrieve Data from the `CategoriesBLL` Class s `GetCategories` Method (Click to view full-size image)

Figure 8: Set the Drop-Down Lists in the UPDATE, INSERT, and DELETE Tabs to (None) (Click to view full-size image)

After completing the ObjectDataSource wizard, configure the DropDownList to display the `CategoryName` data field and to use the `CategoryID` field as the `Value` for each `ListItem`.

At this point, the DropDownList and ObjectDataSource s declarative markup should similar to the following:

```
<asp:DropDownList ID="Categories" runat="server" AutoPostBack="True"
    DataSourceID="CategoriesDataSource" DataTextField="CategoryName"
    DataValueField="CategoryID">
</asp:DropDownList>
<asp:ObjectDataSource ID="CategoriesDataSource" runat="server"
    OldValuesParameterFormatString="original_{0}"
    SelectMethod="GetCategories" TypeName="CategoriesBLL">
</asp:ObjectDataSource>
```

Next, drag a GridView onto the Designer, placing it beneath the DropDownList. Set the GridView s `ID` to `ProductsByCategory` and, from its smart tag, bind it to a new ObjectDataSource named `ProductsByCategoryDataSource`. Configure the `ProductsByCategoryDataSource` ObjectDataSource to use the `ProductsBLLWithSprocs` class, having it retrieve its data using the `GetProductsByCategoryID(categoryID)` method. Since this GridView will only be used to display data, set the drop-down lists in the UPDATE, INSERT, and DELETE tabs to (None) and click Next.

Figure 9: Configure the ObjectDataSource to Use the `ProductsBLLWithSprocs` Class (Click to view full-size image)

Figure 10: Retrieve Data from the `GetProductsByCategoryID(categoryID)` Method (Click to view full-size image)

The method chosen in the SELECT tab expects a parameter, so the final step of the wizard prompts us for the parameter s source. Set the Parameter source drop-down list to Control and choose the `Categories` control from the ControlID drop-down list. Click Finish to complete the wizard.

Figure 11: Use the `Categories` DropDownList as the Source of the `categoryID` Parameter (Click to view full-size image)

Upon completing the ObjectDataSource wizard, Visual Studio will add BoundFields and a CheckBoxField for each of the product data fields. Feel free to customize these fields as you see fit.

Visit the page through a browser. When visiting the page the Beverages category is selected and the corresponding products listed in the grid. Changing the drop-down list to an alternative category, as Figure 12 shows, causes a postback and reloads the grid with the products of the newly selected category.

Figure 12: The Products in the Produce Category are Displayed (Click to view full-size image)

Step 5: Wrapping a Stored Procedure s Statements Within the Scope of a Transaction

In the Wrapping Database Modifications within a Transaction tutorial we discussed techniques for performing a series of database modification statements within the scope of a transaction. Recall that the modifications performed under the umbrella of a transaction either all succeed or all fail, guaranteeing atomicity. Techniques for using transactions include:

- Using the classes in the `System.Transactions` namespace,
- Having the Data Access Layer use ADO.NET classes like `SqlTransaction`, and
- Adding the T-SQL transaction commands directly within the stored procedure

The *Wrapping Database Modifications within a Transaction* tutorial used the ADO.NET classes in the DAL. The remainder of this tutorial examines how to manage a transaction using T-SQL commands from within a stored procedure.

The three key SQL commands for manually starting, committing, and rolling back a transaction are `BEGIN TRANSACTION`, `COMMIT TRANSACTION`, and `ROLLBACK TRANSACTION`, respectively. Like with the ADO.NET approach, when using transactions from within a stored procedure we need to apply the following pattern:

1. Indicate the start of a transaction.
2. Execute the SQL statements that comprise the transaction.
3. If there is an error in any one of the statements from Step 2, rollback the transaction.
4. If all of the statements from Step 2 complete without error, commit the transaction.

This pattern can be implemented in T-SQL syntax using the following template:

```
BEGIN TRY
  BEGIN TRANSACTION -- Start the transaction
  ... Perform the SQL statements that makeup the transaction ...
  -- If we reach here, success!
  COMMIT TRANSACTION
END TRY
BEGIN CATCH
  -- Whoops, there was an error
  ROLLBACK TRANSACTION
  -- Raise an error with the
  -- details of the exception
  DECLARE @ErrMsg nvarchar(4000),
          @ErrSeverity int
  SELECT @ErrMsg = ERROR_MESSAGE(),
         @ErrSeverity = ERROR_SEVERITY()

  RAISERROR(@ErrMsg, @ErrSeverity, 1)
END CATCH
```

The template starts by defining a `TRY...CATCH` block, a construct new to SQL Server 2005. Like with `Try...Catch` blocks in Visual Basic, the SQL `TRY...CATCH` block executes the statements in the `TRY` block. If any statement raises an error, control is immediately transferred to the `CATCH` block.

If there are no errors executing the SQL statements that makeup the transaction, the `COMMIT TRANSACTION` statement commits the changes and completes the transaction. If, however, one of the statements results in an error, the `ROLLBACK TRANSACTION` in the `CATCH` block returns the database to its state prior to the start of the transaction. The stored procedure also raises an error using the RAISERROR command, which causes a `SqlException` to be raised in the application.

> **NOTE**
> Since the `TRY...CATCH` block is new to SQL Server 2005, the above template will not work if you are using older versions of Microsoft SQL Server. If you are not using SQL Server 2005, consult Managing Transactions in SQL Server Stored Procedures for a template that will work with other versions of SQL Server.

Let s look at a concrete example. A foreign key constraint exists between the `Categories` and `Products` tables, meaning that each `CategoryID` field in the `Products` table must map to a `CategoryID` value in the `Categories` table. Any action that would violate this constraint, such as attempting to delete a category that has associated products, results in a foreign key constraint violation. To verify this, revisit the Updating and Deleting Existing Binary Data example in the Working with Binary Data section (`~/BinaryData/UpdatingAndDeleting.aspx`). This page lists each category in the system along with Edit and Delete buttons (see Figure 13), but if you attempt to delete a category that has associated products - such as Beverages - the delete fails due to a foreign key constraint violation (see Figure 14).

Figure 13: Each Category is Displayed in a GridView with Edit and Delete Buttons (Click to view full-size image)

Figure 14: You Cannot Delete a Category that has Existing Products (Click to view full-size image)

Imagine, though, that we want to allow categories to be deleted regardless of whether they have associated products. Should a category with products be deleted, imagine that we want to also delete its existing products (although another option would be to simply set its products `CategoryID` values to `NULL`). This functionality could be implemented through the cascade rules of the foreign key constraint. Alternatively, we could create a stored procedure that accepts a `@CategoryID` input parameter and, when invoked, explicitly deletes all of the associated products and then the specified category.

Our first attempt at such a stored procedure might look like the following:

```
CREATE PROCEDURE dbo.Categories_Delete
(
    @CategoryID int
)
AS
-- First, delete the associated products...
DELETE FROM Products
WHERE CategoryID = @CategoryID
-- Now delete the category
DELETE FROM Categories
WHERE CategoryID = @CategoryID
```

While this will definitely delete the associated products and category, it does not do so under the umbrella of a transaction. Imagine that there is some other foreign key constraint on `Categories` that would prohibit the deletion of a particular `@CategoryID` value. The problem is that in such a case all of the products will be deleted before we attempt to delete the category. The net result is that for such a category, this stored procedure would remove all of its products while the category remained since it still has related records in some other table.

If the stored procedure were wrapped within the scope of a transaction, however, the deletes to the `Products` table would be rolled back in the face of a failed delete on `Categories`. The following stored procedure script uses a transaction to assure atomicity between the two `DELETE` statements:

```
CREATE PROCEDURE dbo.Categories_Delete
(
    @CategoryID int
)
AS
BEGIN TRY
  BEGIN TRANSACTION -- Start the transaction
  -- First, delete the associated products...
  DELETE FROM Products
  WHERE CategoryID = @CategoryID
  -- Now delete the category
  DELETE FROM Categories
  WHERE CategoryID = @CategoryID
  -- If we reach here, success!
  COMMIT TRANSACTION
END TRY
BEGIN CATCH
  -- Whoops, there was an error
  ROLLBACK TRANSACTION
  -- Raise an error with the
  -- details of the exception
  DECLARE @ErrMsg nvarchar(4000),
          @ErrSeverity int
  SELECT @ErrMsg = ERROR_MESSAGE(),
         @ErrSeverity = ERROR_SEVERITY()

  RAISERROR(@ErrMsg, @ErrSeverity, 1)
END CATCH
```

Take a moment to add the `Categories_Delete` stored procedure to the Northwind database. Refer back to Step 1 for instructions on adding stored procedures to a database.

Step 6: Updating the `CategoriesTableAdapter`

While we ve added the `Categories_Delete` stored procedure to the database, the DAL is currently configured to use ad-hoc SQL statements to perform the delete. We need to update the `CategoriesTableAdapter` and instruct it to use the `Categories_Delete` stored procedure instead.

> **NOTE**
>
> Earlier in this tutorial we were working with the `NorthwindWithSprocs` DataSet. But that DataSet only has a single entity, `ProductsDataTable`, and we need to work with categories. Therefore, for the remainder of this tutorial when I talk about the Data Access Layer I m referring to the `Northwind` DataSet, the one that we first created in the Creating a Data Access Layer tutorial.

Open the Northwind DataSet, select the `CategoriesTableAdapter`, and go to the Properties window. The Properties window lists the `InsertCommand`, `UpdateCommand`, `DeleteCommand`, and `SelectCommand` used by the TableAdapter, as well as its name and connection information. Expand the `DeleteCommand` property to see its details. As Figure 15 shows, the `DeleteCommand` s `CommandType` property is set to Text, which instructs it to send the text in the `CommandText` property as an ad-hoc SQL query.

Figure 15: Select the `CategoriesTableAdapter` in the Designer to View Its Properties in the Properties Window

To change these settings, select the (DeleteCommand) text in the Properties window and choose (New) from the drop-down list. This will clear out the settings for the `CommandText`, `CommandType`, and `Parameters` properties. Next, set the `CommandType` property to `StoredProcedure` and then type in the name of the stored procedure for the `CommandText` (`dbo.Categories_Delete`). If you make sure to enter the properties in this order - first the `CommandType` and then the `CommandText` - Visual Studio will automatically populate the Parameters collection. If you do not enter these properties in this order, you will have to manually add the parameters through the Parameters Collection Editor. In either case, it s prudent to click on the ellipses in the Parameters property to bring up the Parameters Collection Editor to verify that the correct parameter settings changes have been made (see Figure 16). If you do not see any parameters in the dialog box, add the `@CategoryID` parameter manually (you do not need to add the `@RETURN_VALUE` parameter).

Figure 16: Ensure That the Parameters Settings are Correct

Once the DAL has been updated, deleting a category will automatically delete all of its associated products and do so under the umbrella of a transaction. To verify this, return to the Updating and Deleting Existing Binary Data page and click the Delete button for one of the categories. With one single click of the mouse, the category and all of its associated products will be deleted.

> **NOTE**
>
> Before testing the `Categories_Delete` stored procedure, which will delete a number of products along with the selected category, it might be prudent to make a backup copy of your database. If you are using the `NORTHWND.MDF` database in `App_Data`, simply close Visual Studio and copy the MDF and LDF files in `App_Data` to some other folder. After testing the functionality, you can restore the database by closing Visual Studio and replacing the current MDF and LDF files in `App_Data` with the backup copies.

Summary

While the TableAdapter s wizard will automatically generate stored procedures for us, there are times when we might already have such stored procedures created or want to create them manually or with other tools instead. To accommodate such scenarios, the TableAdapter can also be configured to point to an existing stored procedure. In this tutorial we looked at how to manually add stored procedures to a database through the Visual Studio environment and how to wire the TableAdapter s methods to these stored procedures. We also examined the T-SQL commands and script pattern used for starting, committing, and rolling back transactions from within a stored procedure.

Updating the TableAdapter to Use JOINs (VB)

2/20/2020 • 17 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

When working with a database it is common to request data that is spread across multiple tables. To retrieve data from two different tables we can use either a correlated subquery or a JOIN operation. In this tutorial we compare correlated subqueries and the JOIN syntax before looking at how to create a TableAdapter that includes a JOIN in its main query.

Introduction

With relational databases the data we are interested in working with is often spread across multiple tables. For example, when displaying product information we likely want to list each product s corresponding category and supplier s names. The `Products` table has `CategoryID` and `SupplierID` values, but the actual category and supplier names are in the `Categories` and `Suppliers` tables, respectively.

To retrieve information from another, related table, we can either use *correlated subqueries* or `JOIN` *s*. A correlated subquery is a nested `SELECT` query that references columns in the outer query. For example, in the Creating a Data Access Layer tutorial we used two correlated subqueries in the `ProductsTableAdapter` s main query to return the category and supplier names for each product. A `JOIN` is a SQL construct that merges related rows from two different tables. We used a `JOIN` in the Querying Data with the SqlDataSource Control tutorial to display category information alongside each product.

The reason we have abstained from using `JOIN` s with the TableAdapters is because of limitations in the TableAdapter s wizard to auto-generate corresponding `INSERT`, `UPDATE`, and `DELETE` statements. More specifically, if the TableAdapter s main query contains any `JOIN` s, the TableAdapter cannot auto-create the ad-hoc SQL statements or stored procedures for its `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties.

In this tutorial we will briefly compare and contrast correlated subqueries and `JOIN` s before exploring how to create a TableAdapter that includes `JOIN` s in its main query.

Comparing and Contrasting Correlated Subqueries and `JOIN` s

Recall that the `ProductsTableAdapter` created in the first tutorial in the `Northwind` DataSet uses correlated subqueries to bring back each product s corresponding category and supplier name. The `ProductsTableAdapter` s main query is shown below.

```
SELECT ProductID, ProductName, SupplierID, CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued,
       (SELECT CategoryName FROM Categories WHERE Categories.CategoryID =
            Products.CategoryID) as CategoryName,
       (SELECT CompanyName FROM Suppliers WHERE Suppliers.SupplierID =
            Products.SupplierID) as SupplierName
FROM Products
```

The two correlated subqueries -

`(SELECT CategoryName FROM Categories WHERE Categories.CategoryID = Products.CategoryID)` and

`(SELECT CompanyName FROM Suppliers WHERE Suppliers.SupplierID = Products.SupplierID)` - are `SELECT` queries that return a single value per product as an additional column in the outer `SELECT` statement s column list.

Alternatively, a `JOIN` can be used to return each product s supplier and category name. The following query returns the same output as the above one, but uses `JOIN` s in place of subqueries:

```
SELECT ProductID, ProductName, Products.SupplierID, Products.CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued,
       Categories.CategoryName,
       Suppliers.CompanyName as SupplierName
FROM Products
    LEFT JOIN Categories ON
        Categories.CategoryID = Products.CategoryID
    LEFT JOIN Suppliers ON
        Suppliers.SupplierID = Products.SupplierID
```

A `JOIN` merges the records from one table with records from another table based on some criteria. In the above query, for example, the `LEFT JOIN Categories ON Categories.CategoryID = Products.CategoryID` instructs SQL Server to merge each product record with the category record whose `CategoryID` value matches the product s `CategoryID` value. The merged result allows us to work with the corresponding category fields for each product (such as `CategoryName`).

NOTE

`JOIN` s are commonly used when querying data from relational databases. If you are new to the `JOIN` syntax or need to brush up a bit on its usage, I d recommend the SQL Join tutorial at W3 Schools. Also worth reading are the `JOIN` Fundamentals and Subquery Fundamentals sections of the SQL Books Online.

Since `JOIN` s and correlated subqueries can both be used to retrieve related data from other tables, many developers are left scratching their heads and wondering which approach to use. All of the SQL gurus I ve talked to have said roughly the same thing, that it doesn t really matter performance-wise as SQL Server will produce roughly identical execution plans. Their advice, then, is to use the technique that you and your team are most comfortable with. It merits noting that after imparting this advice these experts immediately express their preference of `JOIN` s over correlated subqueries.

When building a Data Access Layer using Typed DataSets, the tools work better when using subqueries. In particular, the TableAdapter s wizard will not auto-generate corresponding `INSERT`, `UPDATE`, and `DELETE` statements if the main query contains any `JOIN` s, but will auto-generate these statements when correlated subqueries are used.

To explore this shortcoming, create a temporary Typed DataSet in the `~/App_Code/DAL` folder. During the TableAdapter Configuration wizard, choose to use ad-hoc SQL statements and enter the following `SELECT` query (see Figure 1):

```
SELECT ProductID, ProductName, Products.SupplierID, Products.CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued,
       Categories.CategoryName,
       Suppliers.CompanyName as SupplierName
FROM Products
    LEFT JOIN Categories ON
        Categories.CategoryID = Products.CategoryID
    LEFT JOIN Suppliers ON
        Suppliers.SupplierID = Products.SupplierID
```

Figure 1: Enter a Main Query that Contains `JOIN` s (Click to view full-size image)

By default, the TableAdapter will automatically create `INSERT`, `UPDATE`, and `DELETE` statements based on the main query. If you click the Advanced button you can see that this feature is enabled. Despite this setting, the TableAdapter will not be able to create the `INSERT`, `UPDATE`, and `DELETE` statements because the main query contains a `JOIN`.

Figure 2: Enter a Main Query that Contains `JOIN` s

Click Finish to complete the wizard. At this point your DataSet s Designer will include a single TableAdapter with a DataTable with columns for each of the fields returned in the `SELECT` query s column list. This includes the `CategoryName` and `SupplierName`, as Figure 3 shows.

Figure 3: The DataTable Includes a Column for Each Field Returned in the Column List

While the DataTable has the appropriate columns, the TableAdapter lacks values for its `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties. To confirm this, click on the TableAdapter in the Designer and then go to the Properties window. There you will see that the `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties are set to (None) .

Figure 4: The `InsertCommand`, `UpdateCommand`, and `DeleteCommand` Properties are Set to (None) (Click to view full-size image)

To work around this shortcoming, we can manually provide the SQL statements and parameters for the `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties via the Properties window. Alternatively, we could start by configuring the TableAdapter s main query to *not* include any `JOIN` s. This will allow the `INSERT`, `UPDATE`, and `DELETE` statements to be auto-generated for us. After completing the wizard, we could then manually

update the TableAdapter s `SelectCommand` from the Properties window so that it includes the `JOIN` syntax.

While this approach works, it is very brittle when using ad-hoc SQL queries because any time the TableAdapter s main query is re-configured through the wizard, the auto-generated `INSERT`, `UPDATE`, and `DELETE` statements are recreated. That means all of the customizations we later made would be lost if we right-clicked on the TableAdapter, chose Configure from the context menu, and completed the wizard again.

The brittleness of the TableAdapter s auto-generated `INSERT`, `UPDATE`, and `DELETE` statements is, fortunately, limited to ad-hoc SQL statements. If your TableAdapter uses stored procedures, you can customize the `SelectCommand`, `InsertCommand`, `UpdateCommand`, or `DeleteCommand` stored procedures and re-run the TableAdapter Configuration wizard without having to fear that the stored procedures will be modified.

Over the next several steps we will create a TableAdapter that, initially, uses a main query that omits any `JOIN` s so that the corresponding insert, update, and delete stored procedures will be auto-generated. We will then update the `SelectCommand` so that uses a `JOIN` that returns additional columns from related tables. Finally, we'll create a corresponding Business Logic Layer class and demonstrate using the TableAdapter in an ASP.NET web page.

Step 1: Creating the TableAdapter Using a Simplified Main Query

For this tutorial we will add a TableAdapter and strongly-typed DataTable for the `Employees` table in the `NorthwindWithSprocs` DataSet. The `Employees` table contains a `ReportsTo` field that specified the `EmployeeID` of the employee s manager. For example, employee Anne Dodsworth has a `ReportTo` value of 5, which is the `EmployeeID` of Steven Buchanan. Consequently, Anne reports to Steven, her manager. Along with reporting each employee s `ReportsTo` value, we might also want to retrieve the name of their manager. This can be accomplished using a `JOIN`. But using a `JOIN` when initially creating the TableAdapter precludes the wizard from automatically generating the corresponding insert, update, and delete capabilities. Therefore, we will start by creating a TableAdapter whose main query does not contain any `JOIN` s. Then, in Step 2, we will update the main query stored procedure to retrieve the manager s name via a `JOIN`.

Start by opening the `NorthwindWithSprocs` DataSet in the `~/App_Code/DAL` folder. Right-click on the Designer, select the Add option from the context menu, and pick the TableAdapter menu item. This will launch the TableAdapter Configuration wizard. As Figure 5 depicts, have the wizard create new stored procedures and click Next. For a refresher on creating new stored procedures from the TableAdapter s wizard, consult the Creating New Stored Procedures for the Typed DataSet s TableAdapters tutorial.

Figure 5: Select the Create new stored procedures Option (Click to view full-size image)

Use the following `SELECT` statement for the TableAdapter s main query:

```
SELECT EmployeeID, LastName, FirstName, Title, HireDate, ReportsTo, Country
FROM Employees
```

Since this query does not include any `JOIN` s, the TableAdapter wizard will automatically create stored procedures with corresponding `INSERT`, `UPDATE`, and `DELETE` statements, as well as a stored procedure for executing the main query.

The following step allows us to name the TableAdapter s stored procedures. Use the names `Employees_Select`, `Employees_Insert`, `Employees_Update`, and `Employees_Delete`, as shown in Figure 6.

Figure 6: Name the TableAdapter s Stored Procedures (Click to view full-size image)

The final step prompts us to name the TableAdapter s methods. Use `Fill` and `GetEmployees` as the method names. Also be sure to leave the Create methods to send updates directly to the database (GenerateDBDirectMethods) checkbox checked.

Figure 7: Name the TableAdapter s Methods `Fill` and `GetEmployees` (Click to view full-size image)

After completing the wizard, take a moment to examine the stored procedures in the database. You should see four new ones: `Employees_Select`, `Employees_Insert`, `Employees_Update`, and `Employees_Delete`. Next, inspect the `EmployeesDataTable` and `EmployeesTableAdapter` just created. The DataTable contains a column for each field returned by the main query. Click on the TableAdapter and then go to the Properties window. There you will see that the `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties are correctly configured to call the corresponding stored procedures.

Figure 8: The TableAdapter Includes Insert, Update, and Delete Capabilities (Click to view full-size image)

With the insert, update, and delete stored procedures automatically created and the `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties correctly configured, we are ready to customize the `SelectCommand` s stored procedure to return additional information about each employee s manager. Specifically, we need to update the `Employees_Select` stored procedure to use a `JOIN` and return the manager s `FirstName` and `LastName` values. After the stored procedure has been updated, we will need to update the DataTable so that it includes these additional columns. We'll tackle these two tasks in Steps 2 and 3.

Step 2: Customizing the Stored Procedure to Include a `JOIN`

Start by going to the Server Explorer, drilling down into the Northwind database s Stored Procedures folder, and opening the `Employees_Select` stored procedure. If you do not see this stored procedure, right-click on the Stored Procedures folder and choose Refresh. Update the stored procedure so that it uses a `LEFT JOIN` to return the manager s first and last name:

```
SELECT Employees.EmployeeID, Employees.LastName,
       Employees.FirstName, Employees.Title,
       Employees.HireDate, Employees.ReportsTo,
       Employees.Country,
       Manager.FirstName as ManagerFirstName,
       Manager.LastName as ManagerLastName
FROM Employees
    LEFT JOIN Employees AS Manager ON
        Employees.ReportsTo = Manager.EmployeeID
```

After updating the `SELECT` statement, save the changes by going to the File menu and choosing Save `Employees_Select`. Alternatively, you can click the Save icon in the toolbar or hit Ctrl+S. After saving your changes, right-click on the `Employees_Select` stored procedure in the Server Explorer and choose Execute. This will run the stored procedure and show its results in the Output window (see Figure 9).

Figure 9: The Stored Procedures Results are Displayed in the Output Window (Click to view full-size image)

Step 3: Updating the DataTable s Columns

At this point, the `Employees_Select` stored procedure returns `ManagerFirstName` and `ManagerLastName` values, but the `EmployeesDataTable` is missing these columns. These missing columns can be added to the DataTable in one of two ways:

- **Manually** - right-click on the DataTable in the DataSet Designer and, from the Add menu, choose Column. You can then name the column and set its properties accordingly.
- **Automatically** - the TableAdapter Configuration wizard will update the DataTable s columns to reflect the fields returned by the `SelectCommand` stored procedure. When using ad-hoc SQL statements, the wizard will also remove the `InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties since the `SelectCommand` now contains a `JOIN`. But when using stored procedures, these command properties remain intact.

We have explored manually adding DataTable columns in previous tutorials, including Master/Detail Using a Bulleted List of Master Records with a Details DataList and Uploading Files, and we will look at this process again in more detail in our next tutorial. For this tutorial, however, let s use the automatic approach via the TableAdapter Configuration wizard.

Start by right-clicking on the `EmployeesTableAdapter` and selecting Configure from the context menu. This brings up the TableAdapter Configuration wizard, which lists the stored procedures used for selecting, inserting, updating, and deleting, along with their return values and parameters (if any). Figure 10 shows this wizard. Here we can see that the `Employees_Select` stored procedure now returns the `ManagerFirstName` and `ManagerLastName` fields.

Figure 10: The Wizard Shows the Updated Column List for the `Employees_Select` Stored Procedure (Click to view full-size image)

Complete the wizard by clicking Finish. Upon returning to the DataSet Designer, the `EmployeesDataTable` includes two additional columns: `ManagerFirstName` and `ManagerLastName`.

Figure 11: The `EmployeesDataTable` Contains Two New Columns (Click to view full-size image)

To illustrate that the updated `Employees_Select` stored procedure is in effect and that the insert, update, and delete capabilities of the TableAdapter are still functional, let s create a web page that allows users to view and delete employees. Before we create such a page, however, we need to first create a new class in the Business Logic Layer for working with employees from the `NorthwindWithSprocs` DataSet. In Step 4, we will create an `EmployeesBLLWithSprocs` class. In Step 5, we will use this class from an ASP.NET page.

Step 4: Implementing the Business Logic Layer

Create a new class file in the `~/App_Code/BLL` folder named `EmployeesBLLWithSprocs.vb`. This class mimics the semantics of the existing `EmployeesBLL` class, only this new one provides fewer methods and uses the `NorthwindWithSprocs` DataSet (instead of the `Northwind` DataSet). Add the following code to the `EmployeesBLLWithSprocs` class.

```
Imports NorthwindWithSprocsTableAdapters
<System.ComponentModel.DataObject()> _
Public Class EmployeesBLLWithSprocs
    Private _employeesAdapter As EmployeesTableAdapter = Nothing
    Protected ReadOnly Property Adapter() As EmployeesTableAdapter
        Get
            If _employeesAdapter Is Nothing Then
                _employeesAdapter = New EmployeesTableAdapter()
            End If
            Return _employeesAdapter
        End Get
    End Property
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Select, True)> _
    Public Function GetEmployees() As NorthwindWithSprocs.EmployeesDataTable
        Return Adapter.GetEmployees()
    End Function
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Delete, True)> _
    Public Function DeleteEmployee(ByVal employeeID As Integer) As Boolean
        Dim rowsAffected = Adapter.Delete(employeeID)
        'Return true if precisely one row was deleted, otherwise false
        Return rowsAffected = 1
    End Function
End Class
```

The `EmployeesBLLWithSprocs` class s `Adapter` property returns an instance of the `NorthwindWithSprocs` DataSet s `EmployeesTableAdapter`. This is used by the class s `GetEmployees` and `DeleteEmployee` methods. The `GetEmployees` method calls the `EmployeesTableAdapter` s corresponding `GetEmployees` method, which invokes the `Employees_Select` stored procedure and populates its results in an `EmployeeDataTable`. The `DeleteEmployee` method similarly calls the `EmployeesTableAdapter` s `Delete` method, which invokes the `Employees_Delete` stored procedure.

Step 5: Working with the Data in the Presentation Layer

With the `EmployeesBLLWithSprocs` class complete, we re ready to work with employee data through an ASP.NET page. Open the `JOINs.aspx` page in the `AdvancedDAL` folder and drag a GridView from the Toolbox onto the Designer, setting its `ID` property to `Employees`. Next, from the GridView s smart tag, bind the grid to a new ObjectDataSource control named `EmployeesDataSource`.

Configure the ObjectDataSource to use the `EmployeesBLLWithSprocs` class and, from the SELECT and DELETE tabs, ensure that the `GetEmployees` and `DeleteEmployee` methods are selected from the drop-down lists. Click Finish to complete the ObjectDataSource s configuration.

Figure 12: Configure the ObjectDataSource to Use the `EmployeesBLLWithSprocs` Class (Click to view full-size image)

Figure 13: Have the ObjectDataSource Use the `GetEmployees` and `DeleteEmployee` Methods (Click to view full-size image)

Visual Studio will add a BoundField to the GridView for each of the `EmployeesDataTable` s columns. Remove all of these BoundFields except for `Title`, `LastName`, `FirstName`, `ManagerFirstName`, and `ManagerLastName` and rename the `HeaderText` properties for the last four BoundFields to Last Name, First Name, Manager s First Name, and Manager s Last Name, respectively.

To allow users to delete employees from this page we need to do two things. First, instruct the GridView to provide deleting capabilities by checking the Enable Deleting option from its smart tag. Second, change the ObjectDataSource s `OldValuesParameterFormatString` property from the value set by the ObjectDataSource wizard (`original_{0}`) to its default value (`{0}`). After making these changes, your GridView and ObjectDataSource s declarative markup should look similar to the following:

```
<asp:GridView ID="Employees" runat="server" AutoGenerateColumns="False"
    DataKeyNames="EmployeeID" DataSourceID="EmployeesDataSource">
    <Columns>
        <asp:CommandField ShowDeleteButton="True" />
        <asp:BoundField DataField="Title"
            HeaderText="Title"
            SortExpression="Title" />
        <asp:BoundField DataField="LastName"
            HeaderText="Last Name"
            SortExpression="LastName" />
        <asp:BoundField DataField="FirstName"
            HeaderText="First Name"
            SortExpression="FirstName" />
        <asp:BoundField DataField="ManagerFirstName"
            HeaderText="Manager's First Name"
            SortExpression="ManagerFirstName" />
        <asp:BoundField DataField="ManagerLastName"
            HeaderText="Manager's Last Name"
            SortExpression="ManagerLastName" />
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="EmployeesDataSource" runat="server"
    DeleteMethod="DeleteEmployee" OldValuesParameterFormatString="{0}"
    SelectMethod="GetEmployees" TypeName="EmployeesBLLWithSprocs">
    <DeleteParameters>
        <asp:Parameter Name="employeeID" Type="Int32" />
    </DeleteParameters>
</asp:ObjectDataSource>
```

Test out the page by visiting it through a browser. As Figure 14 shows, the page will list each employee and his or her manager s name (assuming they have one).

Figure 14: The `JOIN` in the `Employees_Select` Stored Procedure Returns the Manager s Name (Click to view full-size image)

Clicking the Delete button starts the deleting workflow, which culminates in the execution of the `Employees_Delete` stored procedure. However, the attempted `DELETE` statement in the stored procedure fails because of a foreign key constraint violation (see Figure 15). Specifically, each employee has one or more records in the `Orders` table, causing the delete to fail.

Figure 15: Deleting an Employee That has Corresponding Orders Results in a Foreign Key Constraint Violation (Click to view full-size image)

To allow an employee to be deleted you could:

- Update the foreign key constraint to cascade deletes,
- Manually delete the records from the `Orders` table for the employee(s) you want to delete, or
- Update the `Employees_Delete` stored procedure to first delete the related records from the `Orders` table before deleting the `Employees` record. We discussed this technique in the Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorial.

I leave this as an exercise for the reader.

Summary

When working with relational databases, it is common for queries to pull their data from multiple, related tables. Correlated subqueries and `JOIN` s provide two different techniques for accessing data from related tables in a query. In previous tutorials we most commonly made use of correlated subqueries because the TableAdapter cannot auto-generate `INSERT`, `UPDATE`, and `DELETE` statements for queries involving `JOIN` s. While these values can be provided manually, when using ad-hoc SQL statements any customizations will be overwritten when the TableAdapter Configuration wizard is completed.

Fortunately, TableAdapters created using stored procedures do not suffer from the same brittleness as those created using ad-hoc SQL statements. Therefore, it is feasible to create a TableAdapter whose main query uses a `JOIN` when using stored procedures. In this tutorial we saw how to create such a TableAdapter. We started by using a `JOIN`-less `SELECT` query for the TableAdapter s main query so that the corresponding insert, update, and delete stored procedures would be auto-created. With the TableAdapter s initial configuration complete, we augmented the `SelectCommand` stored procedure to use a `JOIN` and re-ran the TableAdapter Configuration wizard to update the `EmployeesDataTable` s columns.

Re-running the TableAdapter Configuration wizard automatically updated the `EmployeesDataTable` columns to reflect the data fields returned by the `Employees_Select` stored procedure. Alternatively, we could have added these columns manually to the DataTable. We will explore manually adding columns to the DataTable in the next tutorial.

Happy Programming!

Adding Additional DataTable Columns (VB)

2/20/2020 • 14 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

When using the TableAdapter Wizard to create a Typed DataSet, the corresponding DataTable contains the columns returned by the main database query. But there are occasions when the DataTable needs to include additional columns. In this tutorial we learn why stored procedures are recommended when we need additional DataTable columns.

Introduction

When adding a TableAdapter to a Typed DataSet, the corresponding DataTable s schema is determined by the TableAdapter s main query. For example, if the main query returns data fields *A*, *B*, and *C*, the DataTable will have three corresponding columns named *A*, *B*, and *C*. In addition to its main query, a TableAdapter can include additional queries that return, perhaps, a subset of the data based on some parameter. For instance, in addition to the `ProductsTableAdapter` s main query, which returns information about all products, it also contains methods like `GetProductsByCategoryID(categoryID)` and `GetProductByProductID(productID)`, which return specific product information based on a supplied parameter.

The model of having the DataTable s schema reflect the TableAdapter s main query works well if all of the TableAdapter s methods return the same or fewer data fields than those specified in the main query. If a TableAdapter method needs to return additional data fields, then we should expand the DataTable s schema accordingly. In the Master/Detail Using a Bulleted List of Master Records with a Details DataList tutorial we added a method to the `CategoriesTableAdapter` that returned the `CategoryID`, `CategoryName`, and `Description` data fields defined in the main query plus `NumberOfProducts`, an additional data field that reported the number of products associated with each category. We manually added a new column to the `CategoriesDataTable` in order to capture the `NumberOfProducts` data field value from this new method.

As discussed in the Uploading Files tutorial, great care must be taken with TableAdapters that use ad-hoc SQL statements and have methods whose data fields do not precisely match the main query. If the TableAdapter Configuration wizard is re-run, it will update all of the TableAdapter s methods so that their data field list matches the main query. Consequently, any methods with customized column lists will revert to the main query s column list and not return the expected data. This issue does not arise when using stored procedures.

In this tutorial we will look at how to extend a DataTable s schema to include additional columns. Due to the brittleness of the TableAdapter when using ad-hoc SQL statements, in this tutorial we will use stored procedures. Refer to the Creating New Stored Procedures for the Typed DataSet s TableAdapters and Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorials for more information on configuring a TableAdapter to use stored procedures.

Step 1: Adding a `PriceQuartile` Column to the `ProductsDataTable`

In the *Creating New Stored Procedures for the Typed DataSet s TableAdapters* tutorial we created a Typed DataSet named `NorthwindWithSprocs`. This DataSet currently contains two DataTables: `ProductsDataTable` and `EmployeesDataTable`. The `ProductsTableAdapter` has the following three methods:

- `GetProducts` - the main query, which returns all records from the `Products` table

- `GetProductsByCategoryID(categoryID)` - returns all products with the specified *categoryID*.
- `GetProductByProductID(productID)` - returns the particular product with the specified *productID*.

The main query and the two additional methods all return the same set of data fields, namely all of the columns from the `Products` table. There are no correlated subqueries or `JOIN` s pulling related data from the `Categories` or `Suppliers` tables. Therefore, the `ProductsDataTable` has a corresponding column for each field in the `Products` table.

For this tutorial, let s add a method to the `ProductsTableAdapter` named `GetProductsWithPriceQuartile` that returns all of the products. In addition to the standard product data fields, `GetProductsWithPriceQuartile` will also include a `PriceQuartile` data field that indicates under which quartile the product s price falls. For example, those products whose prices are in the most expensive 25% will have a `PriceQuartile` value of 1, while those whose prices fall in the bottom 25% will have a value of 4. Before we worry about creating the stored procedure to return this information, however, we first need to update the `ProductsDataTable` to include a column to hold the `PriceQuartile` results when the `GetProductsWithPriceQuartile` method is used.

Open the `NorthwindWithSprocs` DataSet and right-click on the `ProductsDataTable`. Choose Add from the context-menu and then pick Column.

Figure 1: Add a New Column to the `ProductsDataTable` (Click to view full-size image)

This will add a new column to the DataTable named Column1 of type `System.String`. We need to update this column s name to PriceQuartile and its type to `System.Int32` since it will be used to hold a number between 1 and 4. Select the newly-added column in the `ProductsDataTable` and, from the Properties window, set the `Name` property to PriceQuartile and the `DataType` property to `System.Int32`.

Figure 2: Set the New Column s `Name` and `DataType` Properties (Click to view full-size image)

As Figure 2 shows, there are additional properties that can be set, such as whether the values in the column must be unique, if the column is an auto-increment column, whether or not database `NULL` values are allowed, and so on. Leave these values set to their defaults.

Step 2: Creating the `GetProductsWithPriceQuartile` Method

Now that the `ProductsDataTable` has been updated to include the `PriceQuartile` column, we are ready to create the `GetProductsWithPriceQuartile` method. Start by right-clicking on the TableAdapter and choosing Add Query from the context-menu. This brings up the TableAdapter Query Configuration wizard, which first prompts us as to whether we want to use ad-hoc SQL statements or a new or existing stored procedure. Since we don t yet have a stored procedure that returns the price quartile data, let s allow the TableAdapter to create this stored procedure for us. Select the Create new stored procedure option and click Next.

Figure 3: Instruct the TableAdapter Wizard to Create the Stored Procedure For Us (Click to view full-size image)

In the subsequent screen, shown in Figure 4, the wizard asks us what type of query to add. Since the `GetProductsWithPriceQuartile` method will return all columns and records from the `Products` table, select the SELECT which returns rows option and click Next.

Figure 4: Our Query will be a `SELECT` Statement that Returns Multiple Rows (Click to view full-size image)

Next we are prompted for the `SELECT` query. Enter the following query into the wizard:

```
SELECT ProductID, ProductName, SupplierID, CategoryID,
       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
       ReorderLevel, Discontinued,
       NTILE(4) OVER (ORDER BY UnitPrice DESC) as PriceQuartile
FROM Products
```

The above query uses SQL Server 2005 s new `NTILE` function to divide the results into four groups where the groups are determined by the `UnitPrice` values sorted in descending order.

Unfortunately, the Query Builder does not know how to parse the `OVER` keyword and will display an error when parsing the above query. Therefore, enter the above query directly in the textbox in the wizard without using the Query Builder.

> **NOTE**
> For more information on NTILE and SQL Server 2005 s other ranking functions, see Returning Ranked Results with Microsoft SQL Server 2005 and the Ranking Functions section from the SQL Server 2005 Books Online.

After entering the `SELECT` query and clicking Next, the wizard asks us to provide a name for the stored procedure it will create. Name the new stored procedure `Products_SelectWithPriceQuartile` and click Next.

Figure 5: Name the Stored Procedure `Products_SelectWithPriceQuartile` (Click to view full-size image)

Lastly, we are prompted to name the TableAdapter methods. Leave both the Fill a DataTable and Return a DataTable checkboxes checked and name the methods `FillWithPriceQuartile` and `GetProductsWithPriceQuartile`.

Figure 6: Name the TableAdapter s Methods and Click Finish (Click to view full-size image)

With the `SELECT` query specified and the stored procedure and TableAdapter methods named, click Finish to complete the wizard. At this point you may get a warning or two from the wizard saying that The `OVER` SQL construct or statement is not supported. These warnings can be ignored.

After completing the wizard, the TableAdapter should include the `FillWithPriceQuartile` and `GetProductsWithPriceQuartile` methods and the database should include a stored procedure named `Products_SelectWithPriceQuartile`. Take a moment to verify that the TableAdapter does indeed contain this new method and that the stored procedure has been correctly added to the database. When checking the database, if you do not see the stored procedure try right-clicking on the Stored Procedures folder and choosing Refresh.

Figure 7: Verify that a New Method Has Been Added to the TableAdapter

Figure 8: Ensure that the Database Contains the `Products_SelectWithPriceQuartile` Stored Procedure (Click to view full-size image)

NOTE

One of the benefits of using stored procedures instead of ad-hoc SQL statements is that re-running the TableAdapter Configuration wizard will not modify the stored procedures column lists. Verify this by right-clicking on the TableAdapter, choosing the Configure option from the context-menu to start the wizard, and then clicking Finish to complete it. Next, go to the database and view the `Products_SelectWithPriceQuartile` stored procedure. Note that its column list has not been modified. Had we been using ad-hoc SQL statements, re-running the TableAdapter Configuration wizard would have reverted this query s column list to match the main query column list, thereby removing the NTILE statement from the query used by the `GetProductsWithPriceQuartile` method.

When the Data Access Layer s `GetProductsWithPriceQuartile` method is invoked, the TableAdapter executes the `Products_SelectWithPriceQuartile` stored procedure and adds a row to the `ProductsDataTable` for each returned record. The data fields returned by the stored procedure are mapped to the `ProductsDataTable` s columns. Since there is a `PriceQuartile` data field returned from the stored procedure, its value is assigned to the `ProductsDataTable` s `PriceQuartile` column.

For those TableAdapter methods whose queries do not return a `PriceQuartile` data field, the `PriceQuartile` column s value is the value specified by its `DefaultValue` property. As Figure 2 shows, this value is set to `DBNull`, the default. If you would prefer a different default value, simply set the `DefaultValue` property accordingly. Just make sure that the `DefaultValue` value is valid given the column s `DataType` (i.e., `System.Int32` for the `PriceQuartile` column).

At this point we have performed the necessary steps for adding an additional column to a DataTable. To verify that this additional column works as expected, let s create an ASP.NET page that displays each product s name, price, and price quartile. Before we do that, though, we first need to update the Business Logic Layer to include a method that calls down to the DAL s `GetProductsWithPriceQuartile` method. We will update the BLL next, in Step 3, and then create the ASP.NET page in Step 4.

Step 3: Augmenting the Business Logic Layer

Before we use the new `GetProductsWithPriceQuartile` method from the Presentation Layer, we should first add a corresponding method to the BLL. Open the `ProductsBLLWithSprocs` class file and add the following code:

```
<System.ComponentModel.DataObjectMethodAttribute_
    (System.ComponentModel.DataObjectMethodType.Select, False)> _
Public Function GetProductsWithPriceQuartile() As NorthwindWithSprocs.ProductsDataTable
    Return Adapter.GetProductsWithPriceQuartile()
End Function
```

Like the other data retrieval methods in `ProductsBLLWithSprocs`, the `GetProductsWithPriceQuartile` method simply calls the DAL s corresponding `GetProductsWithPriceQuartile` method and returns its results.

Step 4: Displaying the Price Quartile Information in an ASP.NET Web Page

With the BLL addition complete we re ready to create an ASP.NET page that shows the price quartile for each product. Open the `AddingColumns.aspx` page in the `AdvancedDAL` folder and drag a GridView from the Toolbox onto the Designer, setting its `ID` property to `Products`. From the GridView s smart tag, bind it to a new ObjectDataSource named `ProductsDataSource`. Configure the ObjectDataSource to use the `ProductsBLLWithSprocs` class s `GetProductsWithPriceQuartile` method. Since this will be a read-only grid, set the drop-down lists in the UPDATE, INSERT, and DELETE tabs to (None) .

Figure 9: Configure the ObjectDataSource to Use the `ProductsBLLWithSprocs` Class (Click to view full-size image)

Figure 10: Retrieve Product Information from the `GetProductsWithPriceQuartile` Method (Click to view full-size image)

After completing the Configure Data Source wizard, Visual Studio will automatically add a BoundField or CheckBoxField to the GridView for each of the data fields returned by the method. One of these data fields is `PriceQuartile`, which is the column we added to the `ProductsDataTable` in Step 1.

Edit the GridView s fields, removing all but the `ProductName`, `UnitPrice`, and `PriceQuartile` BoundFields. Configure the `UnitPrice` BoundField to format its value as a currency and have the `UnitPrice` and `PriceQuartile` BoundFields right- and center-aligned, respectively. Finally, update the remaining BoundFields `HeaderText` properties to Product, Price, and Price Quartile, respectively. Also, check the Enable Sorting checkbox from the GridView s smart tag.

After these modifications, the GridView and ObjectDataSource s declarative markup should look like the following:

```
<asp:GridView ID="Products" runat="server" AllowSorting="True"
    AutoGenerateColumns="False" DataKeyNames="ProductID"
    DataSourceID="ProductsDataSource">
    <Columns>
        <asp:BoundField DataField="ProductName" HeaderText="Product"
            SortExpression="ProductName" />
        <asp:BoundField DataField="UnitPrice" DataFormatString="{0:c}"
            HeaderText="Price" HtmlEncode="False"
            SortExpression="UnitPrice">
            <ItemStyle HorizontalAlign="Right" />
        </asp:BoundField>
        <asp:BoundField DataField="PriceQuartile" HeaderText="Price Quartile"
            SortExpression="PriceQuartile">
            <ItemStyle HorizontalAlign="Center" />
        </asp:BoundField>
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="ProductsDataSource" runat="server"
    OldValuesParameterFormatString="original_{0}"
    SelectMethod="GetProductsWithPriceQuartile"
    TypeName="ProductsBLLWithSprocs">
</asp:ObjectDataSource>
```

Figure 11 shows this page when visited through a browser. Note that, initially, the products are ordered by their price in descending order with each product assigned an appropriate `PriceQuartile` value. Of course this data can be sorted by other criteria with the Price Quartile column value still reflecting the product s ranking with respect to price (see Figure 12).

Figure 11: The Products are Ordered by their Prices (Click to view full-size image)

Figure 12: The Products are Ordered by their Names (Click to view full-size image)

> **NOTE**
>
> With a few lines of code we could augment the GridView so that it colored the product rows based on their `PriceQuartile` value. We might color those products in the first quartile a light green, those in the second quartile a light yellow, and so forth. I encourage you to take a moment to add this functionality. If you need a refresher on formatting a GridView, consult the Custom Formatting Based Upon Data tutorial.

An Alternative Approach - Creating Another TableAdapter

As we saw in this tutorial, when adding a method to a TableAdapter that returns data fields other than those spelled out by the main query, we can add corresponding columns to the DataTable. Such an approach, however, works well only if there are a small number of methods in the TableAdapter that return different data fields and if those alternate data fields do not vary too much from the main query.

Rather than adding columns to the DataTable, you can instead add another TableAdapter to the DataSet that contains the methods from the first TableAdapter that return different data fields. For this tutorial, rather than add the `PriceQuartile` column to the `ProductsDataTable` (where it is only used by the `GetProductsWithPriceQuartile` method), we could have added an additional TableAdapter to the DataSet named `ProductsWithPriceQuartileTableAdapter` that used the `Products_SelectWithPriceQuartile` stored procedure as its main query. ASP.NET pages that needed to get product information with the price quartile would use the `ProductsWithPriceQuartileTableAdapter`, while those that did not could continue to use the `ProductsTableAdapter`.

By adding a new TableAdapter, the DataTables remain untarnished and their columns precisely mirror the data fields returned by their TableAdapter s methods. However, additional TableAdapters can introduce repetitive tasks and functionality. For example, if those ASP.NET pages that displayed the `PriceQuartile` column also needed to provide insert, update, and delete support, the `ProductsWithPriceQuartileTableAdapter` would need to have its

`InsertCommand`, `UpdateCommand`, and `DeleteCommand` properties properly configured. While these properties would mirror the `ProductsTableAdapter` s, this configuration introduces an extra step. Moreover, there are now two ways to update, delete, or add a product to the database - through the `ProductsTableAdapter` and `ProductsWithPriceQuartileTableAdapter` classes.

The download for this tutorial includes a `ProductsWithPriceQuartileTableAdapter` class in the `NorthwindWithSprocs` DataSet that illustrates this alternative approach.

Summary

In most scenarios, all of the methods in a TableAdapter will return the same set of data fields, but there are times when a particular method or two may need to return an additional field. For example, in the Master/Detail Using a Bulleted List of Master Records with a Details DataList tutorial we added a method to the `CategoriesTableAdapter` that, in addition to the main query s data fields, returned a `NumberOfProducts` field that reported the number of products associated with each category. In this tutorial we looked at adding a method in the `ProductsTableAdapter` that returned a `PriceQuartile` field in addition to the main query s data fields. To capture additional data fields returned by the TableAdapter s methods we need to add corresponding columns to the DataTable.

If you plan on manually adding columns to the DataTable, it is recommended that the TableAdapter use stored procedures. If the TableAdapter uses ad-hoc SQL statements, any time the TableAdapter Configuration wizard is run all of the methods data field lists revert to the data fields returned by the main query. This problem does not extend to stored procedures, which is why they are recommended and were used in this tutorial.

Working with Computed Columns (VB)

2/20/2020 • 18 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

When creating a database table, Microsoft SQL Server allows you to define a computed column whose value is calculated from an expression that usually references other values in the same database record. Such values are read-only at the database, which requires special considerations when working with TableAdapters. In this tutorial we learn how to meet the challenges posed by computed columns.

Introduction

Microsoft SQL Server allows for *computed columns*, which are columns whose values are calculated from an expression that usually references the values from other columns in the same table. As an example, a time tracking data model might have a table named `ServiceLog` with columns including `ServicePerformed`, `EmployeeID`, `Rate`, and `Duration`, among others. While the amount due per service item (being the rate multiplied by the duration) could be calculated through a web page or other programmatic interface, it might be handy to include a column in the `ServiceLog` table named `AmountDue` that reported this information. This column could be created as a normal column, but it would need to be updated anytime the `Rate` or `Duration` column values changed. A better approach would be to make the `AmountDue` column a computed column using the expression `Rate * Duration`. Doing so would cause SQL Server to automatically calculate the `AmountDue` column value whenever it was referenced in a query.

Since a computed column s value is determined by an expression, such columns are read-only and therefore cannot have values assigned to them in `INSERT` or `UPDATE` statements. However, when computed columns are part of the main query for a TableAdapter that uses ad-hoc SQL statements, they are automatically included in the auto-generated `INSERT` and `UPDATE` statements. Consequently, the TableAdapter s `INSERT` and `UPDATE` queries and `InsertCommand` and `UpdateCommand` properties must be updated to remove references to any computed columns.

One challenge of using computed columns with a TableAdapter that uses ad-hoc SQL statements is that the TableAdapter s `INSERT` and `UPDATE` queries are automatically regenerated any time the TableAdapter Configuration wizard is completed. Therefore, the computed columns manually removed from the `INSERT` and `UPDATE` queries will reappear if the wizard is re-run. Although TableAdapters that use stored procedures don t suffer from this brittleness, they do have their own quirks that we will address in Step 3.

In this tutorial we will add a computed column to the `Suppliers` table in the Northwind database and then create a corresponding TableAdapter to work with this table and its computed column. We will have our TableAdapter use stored procedures instead of ad-hoc SQL statements so that our customizations aren't lost when the TableAdapter Configuration wizard is used.

Let s get started!

Step 1: Adding a Computed Column to the `Suppliers` Table

The Northwind database does not have any computed columns so we will need to add one ourselves. For this tutorial let s add a computed column to the `Suppliers` table called `FullContactName` that returns the contact s name, title, and the company they work for in the following format: `ContactName` (`ContactTitle` , `CompanyName`).

This computed column might be used in reports when displaying information about suppliers.

Start by opening the `Suppliers` table definition by right-clicking on the `Suppliers` table in the Server Explorer and choosing Open Table Definition from the context-menu. This will display the columns of the table and their properties, such as their data type, whether they allow `NULL` s, and so forth. To add a computed column, start by typing in the name of the column into the table definition. Next, enter its expression into the (Formula) textbox under the Computed Column Specification section in the Column Properties window (see Figure 1). Name the computed column `FullContactName` and use the following expression:

```
ContactName + ' (' + CASE WHEN ContactTitle IS NOT NULL THEN
    ContactTitle + ', ' ELSE '' END + CompanyName + ')'
```

Note that strings can be concatenated in SQL using the `+` operator. The `CASE` statement can be used like a conditional in a traditional programming language. In the above expression the `CASE` statement can be read as: If `ContactTitle` is not `NULL` then output the `ContactTitle` value concatenated with a comma, otherwise emit nothing. For more on the usefulness of the `CASE` statement, see The Power of SQL `CASE` Statements.

> **NOTE**
>
> Instead of using a `CASE` statement here, we could have alternatively used `ISNULL(ContactTitle, '')`. `ISNULL(checkExpression, replacementValue)` returns *checkExpression* if it is non-NULL, otherwise it returns *replacementValue*. While either `ISNULL` or `CASE` will work in this instance, there are more intricate scenarios where the flexibility of the `CASE` statement cannot be matched by `ISNULL`.

After adding this computed column your screen should look like the screen shot in Figure 1.

Figure 1: Add a Computed Column Named `FullContactName` to the `Suppliers` Table (Click to view full-size image)

After naming the computed column and entering its expression, save the changes to the table by clicking the Save

icon in the toolbar, by hitting Ctrl+S, or by going to the File menu and choosing Save `Suppliers`.

Saving the table should refresh the Server Explorer, including the just-added column in the `Suppliers` table s column list. Furthermore, the expression entered into the (Formula) textbox will automatically adjust to an equivalent expression that strips unnecessary whitespace, surrounds column names with brackets (`[]`), and includes parentheses to more explicitly show the order of operations:

```
((([ContactName]+' (')+case when [ContactTitle] IS NOT NULL
    then [ContactTitle]+', ' else '' end)+[CompanyName])+')')
```

For more information on computed columns in Microsoft SQL Server, refer to the technical documentation. Also check out the How to: Specify Computed Columns for a step-by-step walkthrough of creating computed columns.

> **NOTE**
> By default, computed columns are not physically stored in the table but are instead recalculated each time they are referenced in a query. By checking the Is Persisted checkbox, however, you can instruct SQL Server to physically store the computed column in the table. Doing so allows an index to be created on the computed column, which can improve the performance of queries that use the computed column value in their `WHERE` clauses. See Creating Indexes on Computed Columns for more information.

Step 2: Viewing the Computed Column s Values

Before we start work on the Data Access Layer, let s take a minute to view the `FullContactName` values. From the Server Explorer, right-click on the `Suppliers` table name and choose New Query from the context-menu. This will bring up a Query window that prompts us to choose what tables to include in the query. Add the `Suppliers` table and click Close. Next, check the `CompanyName`, `ContactName`, `ContactTitle`, and `FullContactName` columns from the Suppliers table. Finally, click the red exclamation point icon in the Toolbar to execute the query and view the results.

As Figure 2 shows, the results include `FullContactName`, which lists the `CompanyName`, `ContactName`, and `ContactTitle` columns using the format `ContactName` (`ContactTitle`, `CompanyName`) .

Figure 2: The `FullContactName` Uses the Format `ContactName` (`ContactTitle`, `CompanyName`) (Click to view full-size image)

Step 3: Adding the `SuppliersTableAdapter` to the Data Access Layer

In order to work with the supplier information in our application we need to first create a TableAdapter and DataTable in our DAL. Ideally, this would be accomplished using the same straightforward steps examined in earlier tutorials. However, working with computed columns introduces a few wrinkles that merit discussion.

If you are using a TableAdapter that uses ad-hoc SQL statements, you can simply include the computed column in the TableAdapter s main query via the TableAdapter Configuration wizard. This, however, will auto-generate `INSERT` and `UPDATE` statements that include the computed column. If you attempt to execute one of these methods, a `SqlException` with the message The column *ColumnName* cannot be modified because it is either a computed column or is the result of a UNION operator will be thrown. While the `INSERT` and `UPDATE` statement can be manually adjusted through the TableAdapter s `InsertCommand` and `UpdateCommand` properties, these customizations will be lost whenever the TableAdapter Configuration wizard is re-run.

Due to the brittleness of TableAdapters that use ad-hoc SQL statements, it is recommended that we use stored procedures when working with computed columns. If you are using existing stored procedures, simply configure the TableAdapter as discussed in the Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorial. If you have the TableAdapter wizard create the stored procedures for you, however, it is important to initially omit any computed columns from the main query. If you include a computed column in the main query, the TableAdapter Configuration wizard will inform you, upon completion, that it cannot create the corresponding stored procedures. In short, we need to initially configure the TableAdapter using a computed column-free main query and then manually update the corresponding stored procedure and the TableAdapter s `SelectCommand` to include the computed column. This approach is similar to the one used in the Updating the TableAdapter to Use `JOIN` *s* tutorial.

For this tutorial, let s add a new TableAdapter and have it automatically create the stored procedures for us. Consequently, we will need to initially omit the `FullContactName` computed column from the main query.

Start by opening the `NorthwindWithSprocs` DataSet in the `~/App_Code/DAL` folder. Right-click in the Designer and, from the context-menu, choose to add a new TableAdapter. This will launch the TableAdapter Configuration wizard. Specify the database to query data from (`NORTHWNDConnectionString` from `Web.config`) and click Next. Since we have not yet created any stored procedures for querying or modifying the `Suppliers` table, select the Create new stored procedures option so that the wizard will create them for us and click Next.

Figure 3: Choose the Create new stored procedures Option (Click to view full-size image)

The subsequent step prompts us for the main query. Enter the following query, which returns the `SupplierID` , `CompanyName` , `ContactName` , and `ContactTitle` columns for each supplier. Note that this query purposefully omits the computed column (`FullContactName`); we will update the corresponding stored procedure to include this column in Step 4.

```
SELECT SupplierID, CompanyName, ContactName, ContactTitle
FROM Suppliers
```

After entering the main query and clicking Next, the wizard allows us to name the four stored procedures it will generate. Name these stored procedures `Suppliers_Select` , `Suppliers_Insert` , `Suppliers_Update` , and `Suppliers_Delete` , as Figure 4 illustrates.

Figure 4: Customize the Names of the Auto-Generated Stored Procedures (Click to view full-size image)

The next wizard step allows us to name the TableAdapter s methods and specify the patterns used to access and update data. Leave all three checkboxes checked, but rename the `GetData` method to `GetSuppliers`. Click Finish to complete the wizard.

Figure 5: Rename the `GetData` Method to `GetSuppliers` (Click to view full-size image)

Upon clicking Finish, the wizard will create the four stored procedures and add the TableAdapter and corresponding DataTable to the Typed DataSet.

Step 4: Including the Computed Column in the TableAdapter s Main Query

We now need to update the TableAdapter and DataTable created in Step 3 to include the `FullContactName` computed column. This involves two steps:

1. Updating the `Suppliers_Select` stored procedure to return the `FullContactName` computed column, and
2. Updating the DataTable to include a corresponding `FullContactName` column.

Start by navigating to the Server Explorer and drilling down into the Stored Procedures folder. Open the `Suppliers_Select` stored procedure and update the `SELECT` query to include the `FullContactName` computed column:

```
SELECT SupplierID, CompanyName, ContactName, ContactTitle, FullContactName
FROM Suppliers
```

Save the changes to the stored procedure by clicking the Save icon in the Toolbar, by hitting Ctrl+S, or by choosing the Save `Suppliers_Select` option from the File menu.

Next, return to the DataSet Designer, right-click on the `SuppliersTableAdapter`, and choose Configure from the context-menu. Note that the `Suppliers_Select` column now includes the `FullContactName` column in its Data Columns collection.

Figure 6: Run the TableAdapter s Configuration Wizard to Update the DataTable s Columns (Click to view full-size image)

Click Finish to complete the wizard. This will automatically add a corresponding column to the `SuppliersDataTable`. The TableAdapter wizard is smart enough to detect that the `FullContactName` column is a computed column and therefore read-only. Consequently, it sets the column s `ReadOnly` property to `true`. To verify this, select the column from the `SuppliersDataTable` and then go to the Properties window (see Figure 7). Note that the `FullContactName` column s `DataType` and `MaxLength` properties are also set accordingly.

Figure 7: The `FullContactName` Column is Marked as Read-Only (Click to view full-size image)

Step 5: Adding a `GetSupplierBySupplierID` Method to the TableAdapter

For this tutorial we will create an ASP.NET page that displays the suppliers in an updateable grid. In past tutorials we have updated a single record from the Business Logic Layer by retrieving that particular record from the DAL as a strongly-typed DataTable, updating its properties, and then sending the updated DataTable back to the DAL to propagate the changes to the database. To accomplish this first step - retrieving the record being updated from the DAL - we need to first add a `GetSupplierBySupplierID(supplierID)` method to the DAL.

Right-click on the `SuppliersTableAdapter` in the DataSet Design and choose the Add Query option from the context-menu. As we did in Step 3, let the wizard generate a new stored procedure for us by selecting the Create new stored procedure option (refer back to Figure 3 for a screenshot of this wizard step). Since this method will return a record with multiple columns, indicate that we want to use a SQL query that is a SELECT which returns rows and click Next.

Figure 8: Choose the SELECT which returns rows Option (Click to view full-size image)

The subsequent step prompts us for the query to use for this method. Enter the following, which returns the same data fields as the main query but for a particular supplier.

```
SELECT SupplierID, CompanyName, ContactName, ContactTitle, FullContactName
FROM Suppliers
WHERE SupplierID = @SupplierID
```

The next screen asks us to name the stored procedure that will be auto-generated. Name this stored procedure `Suppliers_SelectBySupplierID` and click Next.

Figure 9: Name the Stored Procedure `Suppliers_SelectBySupplierID` (Click to view full-size image)

Lastly, the wizard prompts us for the data access patterns and method names to use for the TableAdapter. Leave both checkboxes checked, but rename the `FillBy` and `GetDataBy` methods to `FillBySupplierID` and `GetSupplierBySupplierID`, respectively.

Figure 10: Name the TableAdapter Methods `FillBySupplierID` and `GetSupplierBySupplierID` (Click to view full-size image)

Click Finish to complete the wizard.

Step 6: Creating the Business Logic Layer

Before we create an ASP.NET page that uses the computed column created in Step 1, we first need to add the corresponding methods in the BLL. Our ASP.NET page, which we will create in Step 7, will allow users to view and edit suppliers. Therefore, we need our BLL to provide, at minimum, a method to get all of the suppliers and another to update a particular supplier.

Create a new class file named `SuppliersBLLWithSprocs` in the `~/App_Code/BLL` folder and add the following code:

```
Imports NorthwindWithSprocsTableAdapters
<System.ComponentModel.DataObject()> _
Public Class SuppliersBLLWithSprocs
    Private _suppliersAdapter As SuppliersTableAdapter = Nothing
    Protected ReadOnly Property Adapter() As SuppliersTableAdapter
        Get
            If _suppliersAdapter Is Nothing Then
                _suppliersAdapter = New SuppliersTableAdapter()
            End If
            Return _suppliersAdapter
        End Get
    End Property
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Select, True)> _
    Public Function GetSuppliers() As NorthwindWithSprocs.SuppliersDataTable
        Return Adapter.GetSuppliers()
    End Function
    <System.ComponentModel.DataObjectMethodAttribute _
        (System.ComponentModel.DataObjectMethodType.Update, True)> _
    Public Function UpdateSupplier(companyName As String, contactName As String, _
        contactTitle As String, supplierID As Integer) As Boolean
        Dim suppliers As NorthwindWithSprocs.SuppliersDataTable = _
            Adapter.GetSupplierBySupplierID(supplierID)
        If suppliers.Count = 0 Then
            ' no matching record found, return false
            Return False
        End If
        Dim supplier As NorthwindWithSprocs.SuppliersRow = suppliers(0)
        supplier.CompanyName = companyName
        If contactName Is Nothing Then
            supplier.SetContactNameNull()
        Else
            supplier.ContactName = contactName
        End If
        If contactTitle Is Nothing Then
            supplier.SetContactTitleNull()
        Else
            supplier.ContactTitle = contactTitle
        End If
        ' Update the product record
        Dim rowsAffected As Integer = Adapter.Update(supplier)
        ' Return true if precisely one row was updated, otherwise false
        Return rowsAffected = 1
    End Function
End Class
```

Like the other BLL classes, `SuppliersBLLWithSprocs` has a `Protected` `Adapter` property that returns an instance of the `SuppliersTableAdapter` class along with two `Public` methods: `GetSuppliers` and `UpdateSupplier`. The `GetSuppliers` method calls and returns the `SuppliersDataTable` returned by the corresponding `GetSupplier` method in the Data Access Layer. The `UpdateSupplier` method retrieves information about the particular supplier being updated via a call to the DAL s `GetSupplierBySupplierID(supplierID)` method. It then updates the `CategoryName`, `ContactName`, and `ContactTitle` properties and commits these changes to the database by calling the Data Access Layer s `Update` method, passing in the modified `SuppliersRow` object.

NOTE

Except for `SupplierID` and `CompanyName`, all columns in the Suppliers table allow `NULL` values. Therefore, if the passed-in `contactName` or `contactTitle` parameters are `Nothing` we need to set the corresponding `ContactName` and `ContactTitle` properties to a `NULL` database value using the `SetContactNameNull` and `SetContactTitleNull` methods, respectively.

Step 7: Working with the Computed Column from the Presentation Layer

With the computed column added to the `Suppliers` table and the DAL and BLL updated accordingly, we are ready to build an ASP.NET page that works with the `FullContactName` computed column. Start by opening the `ComputedColumns.aspx` page in the `AdvancedDAL` folder and drag a GridView from the Toolbox onto the Designer. Set the GridView s `ID` property to `Suppliers` and, from its smart tag, bind it to a new ObjectDataSource named `SuppliersDataSource`. Configure the ObjectDataSource to use the `SuppliersBLLWithSprocs` class we added back in Step 6 and click Next.

Figure 11: Configure the ObjectDataSource to Use the `SuppliersBLLWithSprocs` Class (Click to view full-size image)

There are only two methods defined in the `SuppliersBLLWithSprocs` class: `GetSuppliers` and `UpdateSupplier`. Ensure that these two methods are specified in the SELECT and UPDATE tabs, respectively, and click Finish to complete the configuration of the ObjectDataSource.

Upon completion of the Data Source Configuration wizard, Visual Studio will add a BoundField for each of the data fields returned. Remove the `SupplierID` BoundField and change the `HeaderText` properties of the `CompanyName`, `ContactName`, `ContactTitle`, and `FullContactName` BoundFields to Company, Contact Name, Title, and Full Contact Name, respectively. From the smart tag, check the Enable Editing checkbox to turn on the GridView s built-in editing capabilities.

In addition to adding BoundFields to the GridView, completion of the Data Source Wizard also causes Visual Studio to set the ObjectDataSource s `OldValuesParameterFormatString` property to original_{0}. Revert this setting back to its default value, {0} .

After making these edits to the GridView and ObjectDataSource, their declarative markup should look similar to the following:

```
<asp:GridView ID="Suppliers" runat="server" AutoGenerateColumns="False"
    DataKeyNames="SupplierID" DataSourceID="SuppliersDataSource">
    <Columns>
        <asp:CommandField ShowEditButton="True" />
        <asp:BoundField DataField="CompanyName"
            HeaderText="Company"
            SortExpression="CompanyName" />
        <asp:BoundField DataField="ContactName"
            HeaderText="Contact Name"
            SortExpression="ContactName" />
        <asp:BoundField DataField="ContactTitle"
            HeaderText="Title"
            SortExpression="ContactTitle" />
        <asp:BoundField DataField="FullContactName"
            HeaderText="Full Contact Name"
            SortExpression="FullContactName"
            ReadOnly="True" />
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="SuppliersDataSource" runat="server"
    SelectMethod="GetSuppliers" TypeName="SuppliersBLLWithSprocs"
        UpdateMethod="UpdateSupplier">
    <UpdateParameters>
        <asp:Parameter Name="companyName" Type="String" />
        <asp:Parameter Name="contactName" Type="String" />
        <asp:Parameter Name="contactTitle" Type="String" />
        <asp:Parameter Name="supplierID" Type="Int32" />
    </UpdateParameters>
</asp:ObjectDataSource>
```

Next, visit this page through a browser. As Figure 12 shows, each supplier is listed in a grid that includes the `FullContactName` column, whose value is simply the concatenation of the other three columns formatted as `ContactName` (`ContactTitle` , `CompanyName`) .

Figure 12: Each Supplier is Listed in the Grid (Click to view full-size image)

Clicking the Edit button for a particular supplier causes a postback and has that row rendered in its editing interface (see Figure 13). The first three columns render in their default editing interface - a TextBox control whose `Text` property is set to the value of the data field. The `FullContactName` column, however, remains as text. When the BoundFields were added to the GridView at the completion of the Data Source Configuration wizard, the `FullContactName` BoundField s `ReadOnly` property was set to `True` because the corresponding `FullContactName` column in the `SuppliersDataTable` has its `ReadOnly` property set to `True` . As noted in Step 4, the `FullContactName` s `ReadOnly` property was set to `True` because the TableAdapter detected that the column was a

computed column.

Figure 13: The `FullContactName` Column is Not Editable (Click to view full-size image)

Go ahead and update the value of one or more of the editable columns and click Update. Note how the `FullContactName` s value is automatically updated to reflect the change.

> **NOTE**
>
> The GridView currently uses BoundFields for the editable fields, resulting in the default editing interface. Since the `CompanyName` field is required, it should be converted into a TemplateField that includes a RequiredFieldValidator. I leave this as an exercise for the interested reader. Consult the Adding Validation Controls to the Editing and Inserting Interfaces tutorial for step-by-step instructions on converting a BoundField to a TemplateField and adding validation controls.

Summary

When defining the schema for a table, Microsoft SQL Server allows the inclusion of computed columns. These are columns whose values are calculated from an expression that usually references the values from other columns in the same record. Since the values for computed columns are based on an expression, they are read-only and cannot be assigned a value in an `INSERT` or `UPDATE` statement. This introduces challenges when using a computed column in the main query of a TableAdapter that tries to automatically generate corresponding `INSERT` , `UPDATE` , and `DELETE` statements.

In this tutorial we discussed techniques for circumventing the challenges posed by computed columns. In particular, we used stored procedures in our TableAdapter to overcome the brittleness inherent in TableAdapters that use ad-hoc SQL statements. When having the TableAdapter wizard create new stored procedures, it is important that we have the main query initially omit any computed columns because their presence prevents the data modification stored procedures from being generated. After the TableAdapter has been initially configured, its `SelectCommand` stored procedure can be retooled to include any computed columns.

Configuring the Data Access Layer's Connection- and Command-Level Settings (VB)

2/20/2020 • 12 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> The TableAdapters within a Typed DataSet automatically take care of connecting to the database, issuing commands, and populating a DataTable with the results. There are occasions however when we want to take care of these details ourselves, and in this tutorial we learn how to access the database connection- and command-level settings in the TableAdapter.

Introduction

Throughout the tutorial series we have used Typed DataSets to implement the Data Access Layer and business objects of our layered architecture. As discussed in the first tutorial, the Typed DataSet s DataTables serve as repositories of data whereas the TableAdapters act as wrappers to communicate with the database to retrieve and modify the underlying data. The TableAdapters encapsulate the complexity involved in working with the database and saves us from having to write code to connect to the database, issue a command, or populate the results into a DataTable.

There are times, however, when we need to burrow into the depths of the TableAdapter and write code that works directly with the ADO.NET objects. In the Wrapping Database Modifications within a Transaction tutorial, for example, we added methods to the TableAdapter for beginning, committing, and rolling back ADO.NET transactions. These methods used an internal, manually-created `SqlTransaction` object that was assigned to the TableAdapter s `SqlCommand` objects.

In this tutorial we will examine how to access the database connection- and command-level settings in the TableAdapter. In particular, we will add functionality to the `ProductsTableAdapter` that enables access to the underlying connection string and command timeout settings.

Working with Data Using ADO.NET

The Microsoft .NET Framework contains a plethora of classes designed specifically to work with data. These classes, found within the `System.Data` namespace, are referred to as the *ADO.NET* classes. Some of the classes under the ADO.NET umbrella are tied to a particular *data provider*. You can think of a data provider as a communication channel that allows information to flow between the ADO.NET classes and the underlying data store. There are generalized providers, like OleDb and ODBC, as well as providers that are specially designed for a particular database system. For example, while it is possible to connect to a Microsoft SQL Server database using the OleDb provider, the SqlClient provider is much more efficient as it was designed and optimized specifically for SQL Server.

When programmatically accessing data, the following pattern is commonly used:

1. Establish a connection to the database.
2. Issue a command.
3. For `SELECT` queries, work with the resulting records.

There are separate ADO.NET classes for performing each of these steps. To connect to a database using the

SqlClient provider, for example, use the `SqlConnection` class. To issue an `INSERT`, `UPDATE`, `DELETE`, or `SELECT` command to the database, use the `SqlCommand` class.

Except for the Wrapping Database Modifications within a Transaction tutorial, we have not had to write any low-level ADO.NET code ourselves because the TableAdapters auto-generated code includes the functionality needed to connect to the database, issue commands, retrieve data, and populate that data into DataTables. However, there may be times when we need to customize these low-level settings. Over the next few steps we will examine how to tap into the ADO.NET objects used internally by the TableAdapters.

Step 1: Examining with the Connection Property

Each TableAdapter class has a `Connection` property that specifies database connection information. This property s data type and `ConnectionString` value are determined by the selections made in the TableAdapter Configuration wizard. Recall that when we first add a TableAdapter to a Typed DataSet this wizard asks us for the database source (see Figure 1). The drop-down list in this first step includes those databases specified in the configuration file as well as any other databases in the Server Explorer s Data Connections. If the database we want to use does not exist in the drop-down list, a new database connection can be specified by clicking the New Connection button and providing the needed connection information.

Figure 1: The First Step of the TableAdapter Configuration Wizard (Click to view full-size image)

Let s take a moment to inspect the code for the TableAdapter s `Connection` property. As noted in the Creating a Data Access Layer tutorial, we can view the auto-generated TableAdapter code by going to the Class View window, drilling down to the appropriate class, and then double-clicking the member name.

Navigate to the Class View window by going to the View menu and choosing Class View (or by typing Ctrl+Shift+C). From the top half of the Class View window, drill down to the `NorthwindTableAdapters` namespace and select the `ProductsTableAdapter` class. This will display the `ProductsTableAdapter` s members in the bottom half of the Class View, as shown in Figure 2. Double-click the `Connection` property to see its code.

Figure 2: Double-Click the Connection Property in the Class View to View Its Auto-Generated Code

The TableAdapter s `Connection` property and other connection-related code follows:

```
Private _connection As System.Data.SqlClient.SqlConnection
Private Sub InitConnection()
    Me._connection = New System.Data.SqlClient.SqlConnection
    Me._connection.ConnectionString = _
        ConfigurationManager.ConnectionStrings("NORTHWNDConnectionString").ConnectionString
End Sub
Friend Property Connection() As System.Data.SqlClient.SqlConnection
    Get
        If (Me._connection Is Nothing) Then
            Me.InitConnection
        End If
        Return Me._connection
    End Get
    Set
        Me._connection = value
        If (Not (Me.Adapter.InsertCommand) Is Nothing) Then
            Me.Adapter.InsertCommand.Connection = value
        End If
        If (Not (Me.Adapter.DeleteCommand) Is Nothing) Then
            Me.Adapter.DeleteCommand.Connection = value
        End If
        If (Not (Me.Adapter.UpdateCommand) Is Nothing) Then
            Me.Adapter.UpdateCommand.Connection = value
        End If
        Dim i As Integer = 0
        Do While (i < Me.CommandCollection.Length)
            If (Not (Me.CommandCollection(i)) Is Nothing) Then
                CType(Me.CommandCollection(i), _
                    System.Data.SqlClient.SqlCommand).Connection = value
            End If
            i = (i + 1)
        Loop
    End Set
End Property
```

When the TableAdapter class is instantiated, the member variable `_connection` is equal to `Nothing`. When the `Connection` property is accessed, it first checks to see if the `_connection` member variable has been instantiated. If it has not, the `InitConnection` method is invoked, which instantiates `_connection` and sets its `ConnectionString` property to the connection string value specified from the TableAdapter Configuration wizard s first step.

The `Connection` property can also be assigned to a `SqlConnection` object. Doing so associates the new `SqlConnection` object with each of the TableAdapter s `SqlCommand` objects.

Step 2: Exposing Connection-Level Settings

The connection information should remain encapsulated within the TableAdapter and not be accessible to other layers in the application architecture. However, there may be scenarios when the TableAdapter s connection-level information needs to be accessible or customizable for a query, user, or ASP.NET page.

Let s extend the `ProductsTableAdapter` in the `Northwind` DataSet to include a `ConnectionString` property that can be used by the Business Logic Layer to read or change the connection string used by the TableAdapter.

> **NOTE**
>
> A *connection string* is a string that specifies database connection information, such as the provider to use, the location of the database, authentication credentials, and other database-related settings. For a list of connection string patterns used by a variety of data stores and providers, see ConnectionStrings.com.

As discussed in the Creating a Data Access Layer tutorial, the Typed DataSet s auto-generated classes can be extended through the use of partial classes. First, create a new subfolder in the project named

`ConnectionAndCommandSettings` underneath the `~/App_Code/DAL` folder.

Figure 3: Add a Subfolder Named `ConnectionAndCommandSettings`

Add a new class file named `ProductsTableAdapter.ConnectionAndCommandSettings.vb` and enter the following code:

```
Namespace NorthwindTableAdapters
    Partial Public Class ProductsTableAdapter
        Public Property ConnectionString() As String
            Get
                Return Me.Connection.ConnectionString
            End Get
            Set(ByVal value As String)
                Me.Connection.ConnectionString = value
            End Set
        End Property
    End Class
End Namespace
```

This partial class adds a `Public` property named `ConnectionString` to the `ProductsTableAdapter` class that allows any layer to read or update the connection string for the TableAdapter s underlying connection.

With this partial class created (and saved), open the `ProductsBLL` class. Go to one of the existing methods and type in `Adapter` and then hit the period key to bring up IntelliSense. You should see the new `ConnectionString` property available in IntelliSense, meaning that you can programmatically read or adjust this value from the BLL.

Exposing the Entire Connection Object

This partial class exposes just one property of the underlying connection object: `ConnectionString`. If you want to make the entire connection object available beyond the confines of the TableAdapter, you can alternatively change the `Connection` property s protection level. The auto-generated code we examined in Step 1 showed that the TableAdapter s `Connection` property is marked as `Friend`, meaning that it can only be accessed by classes in the same assembly. This can be changed, however, via the TableAdapter s `ConnectionModifier` property.

Open the `Northwind` DataSet, click on the `ProductsTableAdapter` in the Designer, and navigate to the Properties window. There you will see the `ConnectionModifier` set to its default value, `Assembly`. To make the `Connection` property available outside of the Typed DataSet s assembly, change the `ConnectionModifier` property to `Public`.

Figure 4: The `Connection` Property s Accessibility Level Can Be Configured via the `ConnectionModifier` Property (Click to view full-size image)

Save the DataSet and then return to the `ProductsBLL` class. As before, go to one of the existing methods and type in `Adapter` and then hit the period key to bring up IntelliSense. The list should include a `Connection` property, meaning that you can now programmatically read or assign any connection-level settings from the BLL.

Step 3: Examining the Command-Related Properties

A TableAdapter consists of a main query that, by default, has auto-generated `INSERT`, `UPDATE`, and `DELETE` statements. This main query s `INSERT`, `UPDATE`, and `DELETE` statements are implemented in the TableAdapter s code as an ADO.NET data adapter object via the `Adapter` property. Like with its `Connection` property, the `Adapter` property s data type is determined by the data provider used. Since these tutorials use the SqlClient provider, the `Adapter` property is of type `SqlDataAdapter`.

The TableAdapter s `Adapter` property has three properties of type `SqlCommand` that it uses to issue the `INSERT`, `UPDATE`, and `DELETE` statements:

- `InsertCommand`
- `UpdateCommand`
- `DeleteCommand`

A `SqlCommand` object is responsible for sending a particular query to the database and has properties like: `CommandText`, which contains the ad-hoc SQL statement or stored procedure to execute; and `Parameters`, which is a collection of `SqlParameter` objects. As we saw back in the Creating a Data Access Layer tutorial, these command objects can be customized through the Properties window.

In addition to its main query, the TableAdapter can include a variable number of methods that, when invoked, dispatch a specified command to the database. The main query s command object and the command objects for all additional methods are stored in the TableAdapter s `CommandCollection` property.

Let s take a moment to look at the code generated by the `ProductsTableAdapter` in the `Northwind` DataSet for these two properties and their supporting member variables and helper methods:

```
Private WithEvents _adapter As System.Data.SqlClient.SqlDataAdapter
Private Sub InitAdapter()
    Me._adapter = New System.Data.SqlClient.SqlDataAdapter

    ... Code that creates the InsertCommand, UpdateCommand, ...
    ... and DeleteCommand instances - omitted for brevity ...
End Sub
Private ReadOnly Property Adapter() As System.Data.SqlClient.SqlDataAdapter
    Get
        If (Me._adapter Is Nothing) Then
            Me.InitAdapter
        End If
        Return Me._adapter
    End Get
End Property
Private _commandCollection() As System.Data.SqlClient.SqlCommand
Private Sub InitCommandCollection()
    Me._commandCollection = New System.Data.SqlClient.SqlCommand(8) {}
    ... Code that creates the command objects for the main query and the ...
    ... ProductsTableAdapter►s other eight methods - omitted for brevity ...
End Sub
Protected ReadOnly Property CommandCollection() As System.Data.SqlClient.SqlCommand()
    Get
        If (Me._commandCollection Is Nothing) Then
            Me.InitCommandCollection
        End If
        Return Me._commandCollection
    End Get
End Property
```

The code for the `Adapter` and `CommandCollection` properties closely mimics that of the `Connection` property. There are member variables that hold the objects used by the properties. The properties `Get` accessors start by checking to see if the corresponding member variable is `Nothing`. If so, an initialization method is called which creates an instance of the member variable and assigns the core command-related properties.

Step 4: Exposing Command-Level Settings

Ideally, the command-level information should remain encapsulated within the Data Access Layer. Should this information be needed in other layers of the architecture, however, it can be exposed through a partial class, just like with the connection-level settings.

Since the TableAdapter only has a single `Connection` property, the code for exposing connection-level settings is fairly straightforward. Things are a bit more complicated when modifying command-level settings because the TableAdapter can have multiple command objects - an `InsertCommand`, `UpdateCommand`, and `DeleteCommand`, along with a variable number of command objects in the `CommandCollection` property. When updating command-level settings, these settings will need to be propagated to all of the command objects.

For example, imagine that there were certain queries in the TableAdapter that took an extraordinary long time to execute. When using the TableAdapter to execute one of those queries, we might want to increase the command object s `CommandTimeout` property. This property specifies the number of seconds to wait for the command to execute and defaults to 30.

To allow the `CommandTimeout` property to be adjusted by the BLL, add the following `Public` method to the `ProductsDataTable` using the partial class file created in Step 2 (`ProductsTableAdapter.ConnectionAndCommandSettings.vb`):

```
Public Sub SetCommandTimeout(ByVal timeout As Integer)
    If Me.Adapter.InsertCommand IsNot Nothing Then
        Me.Adapter.InsertCommand.CommandTimeout = timeout
    End If
    If Me.Adapter.DeleteCommand IsNot Nothing Then
        Me.Adapter.DeleteCommand.CommandTimeout = timeout
    End If
    If Me.Adapter.UpdateCommand IsNot Nothing Then
        Me.Adapter.UpdateCommand.CommandTimeout = timeout
    End If
    For i As Integer = 0 To Me.CommandCollection.Length - 1
        If Me.CommandCollection(i) IsNot Nothing Then
            Me.CommandCollection(i).CommandTimeout = timeout
        End If
    Next
End Sub
```

This method could be invoked from the BLL or Presentation Layer to set the command timeout for all commands issues by that TableAdapter instance.

NOTE

The `Adapter` and `CommandCollection` properties are marked as `Private`, meaning they can only be accessed from code within the TableAdapter. Unlike the `Connection` property, these access modifiers are not configurable. Therefore, if you need to expose command-level properties to other layers in the architecture you must use the partial class approach discussed above to provide a `Public` method or property that reads or writes to the `Private` command objects.

Summary

The TableAdapters within a Typed DataSet serve to encapsulate data access details and complexity. Using TableAdapters, we do not have to worry about writing ADO.NET code to connect to the database, issue a command, or populate the results into a DataTable. It is all handled automatically for us.

However, there may be times when we need to customize the low-level ADO.NET specifics, such as changing the connection string or the default connection or command timeout values. The TableAdapter has auto-generated `Connection`, `Adapter`, and `CommandCollection` properties, but these are either `Friend` or `Private`, by default. This internal information can be exposed by extending the TableAdapter using partial classes to include `Public` methods or properties. Alternatively, the TableAdapter s `Connection` property access modifier can be configured through the TableAdapter s `ConnectionModifier` property.

Protecting Connection Strings and Other Configuration Information (VB)

2/20/2020 • 16 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

An ASP.NET application typically stores configuration information in a Web.config file. Some of this information is sensitive and warrants protection. By default this file will not be served to a Web site visitor, but an administrator or a hacker may gain access to the Web server's file system and view the contents of the file. In this tutorial we learn that ASP.NET 2.0 allows us to protect sensitive information by encrypting sections of the Web.config file.

Introduction

Configuration information for ASP.NET applications is commonly stored in an XML file named `Web.config`. Over the course of these tutorials we have updated the `Web.config` a handful of times. When creating the `Northwind` Typed DataSet in the first tutorial, for example, connection string information was automatically added to `Web.config` in the `<connectionStrings>` section. Later, in the Master Pages and Site Navigation tutorial, we manually updated `Web.config`, adding a `<pages>` element indicating that all of the ASP.NET pages in our project should use the `DataWebControls` Theme.

Since `Web.config` may contain sensitive data such as connection strings, it is important that the contents of `Web.config` be kept safe and hidden from unauthorized viewers. By default, any HTTP request to a file with the `.config` extension is handled by the ASP.NET engine, which returns the *This type of page is not served* message shown in Figure 1. This means that visitors cannot view your `Web.config` file s contents by simply entering http://www.YourServer.com/Web.config into their browser s Address bar.

Figure 1: Visiting `Web.config` Through a Browser Returns a This type of page is not served Message (Click to view full-size image)

But what if an attacker is able to find some other exploit that allows her to view your `Web.config` file s contents? What could an attacker do with this information, and what steps can be taken to further protect the sensitive information within `Web.config`? Fortunately, most sections in `Web.config` do not contain sensitive information. What harm can an attacker perpetrate if they know the name of the default Theme used by your ASP.NET pages?

Certain `Web.config` sections, however, contain sensitive information that may include connection strings, user

names, passwords, server names, encryption keys, and so forth. This information is typically found in the following `Web.config` sections:

- `<appSettings>`
- `<connectionStrings>`
- `<identity>`
- `<sessionState>`

In this tutorial we will look at techniques for protecting such sensitive configuration information. As we will see, the .NET Framework version 2.0 includes a protected configurations system that makes programmatically encrypting and decrypting selected configuration sections a breeze.

> **NOTE**
> This tutorial concludes with a look at Microsoft s recommendations for connecting to a database from an ASP.NET application. In addition to encrypting your connection strings, you can help harden your system by ensuring that you are connecting to the database in a secure fashion.

Step 1: Exploring ASP.NET 2.0 s Protected Configuration Options

ASP.NET 2.0 includes a protected configuration system for encrypting and decrypting configuration information. This includes methods in the .NET Framework that can be used to programmatically encrypt or decrypt configuration information. The protected configuration system uses the provider model, which allows developers to choose what cryptographic implementation is used.

The .NET Framework ships with two protected configuration providers:

- `RSAProtectedConfigurationProvider` - uses the asymmetric RSA algorithm for encryption and decryption.
- `DPAPIProtectedConfigurationProvider` - uses the Windows Data Protection API (DPAPI) for encryption and decryption.

Since the protected configuration system implements the provider design pattern, it is possible to create your own protected configuration provider and plug it into your application. See Implementing a Protected Configuration Provider for more information on this process.

The RSA and DPAPI providers use keys for their encryption and decryption routines, and these keys can be stored at the machine- or user-level. Machine-level keys are ideal for scenarios where the web application runs on its own dedicated server or if there are multiple applications on a server that need to share encrypted information. User-level keys are a more secure option in shared hosting environments where other applications on the same server should not be able to decrypt your application s protected configuration sections.

In this tutorial our examples will use the DPAPI provider and machine-level keys. Specifically, we will look at encrypting the `<connectionStrings>` section in `Web.config`, although the protected configuration system can be used to encrypt most any `Web.config` section. For information on using user-level keys or using the RSA provider, consult the resources in the Further Readings section at the end of this tutorial.

NOTE

The `RSAProtectedConfigurationProvider` and `DPAPIProtectedConfigurationProvider` providers are registered in the `machine.config` file with the provider names `RsaProtectedConfigurationProvider` and `DataProtectionConfigurationProvider`, respectively. When encrypting or decrypting configuration information we will need to supply the appropriate provider name (`RsaProtectedConfigurationProvider` or `DataProtectionConfigurationProvider`) rather than the actual type name (`RSAProtectedConfigurationProvider` and `DPAPIProtectedConfigurationProvider`). You can find the `machine.config` file in the `$WINDOWS$\Microsoft.NET\Framework\version\CONFIG` folder.

Step 2: Programmatically Encrypting and Decrypting Configuration Sections

With a few lines of code we can encrypt or decrypt a particular configuration section using a specified provider. The code, as we will see shortly, simply needs to programmatically reference the appropriate configuration section, call its `ProtectSection` or `UnprotectSection` method, and then call the `Save` method to persist the changes. Moreover, the .NET Framework includes a helpful command line utility that can encrypt and decrypt configuration information. We will explore this command line utility in Step 3.

To illustrate programmatically protecting configuration information, let s create an ASP.NET page that includes buttons for encrypting and decrypting the `<connectionStrings>` section in `Web.config`.

Start by opening the `EncryptingConfigSections.aspx` page in the `AdvancedDAL` folder. Drag a TextBox control from the Toolbox onto the Designer, setting its `ID` property to `WebConfigContents`, its `TextMode` property to `MultiLine`, and its `Width` and `Rows` properties to 95% and 15, respectively. This TextBox control will display the contents of `Web.config` allowing us to quickly see if the contents are encrypted or not. Of course, in a real application you would never want to display the contents of `Web.config`.

Beneath the TextBox, add two Button controls named `EncryptConnStrings` and `DecryptConnStrings`. Set their Text properties to Encrypt Connection Strings and Decrypt Connection Strings .

At this point your screen should look similar to Figure 2.

Figure 2: Add a TextBox and Two Button Web Controls to the Page (Click to view full-size image)

Next, we need to write code that loads and displays the contents of `Web.config` in the `WebConfigContents` TextBox when the page is first loaded. Add the following code to the page s code-behind class. This code adds a method named `DisplayWebConfig` and calls it from the `Page_Load` event handler when `Page.IsPostBack` is `False`:

```
Protected Sub Page_Load(sender As Object, e As EventArgs) Handles Me.Load
    'On the first page visit, call DisplayWebConfig method
    If Not Page.IsPostBack Then
        DisplayWebConfig()
    End If
End Sub
Private Sub DisplayWebConfig()
    'Reads in the contents of Web.config and displays them in the TextBox
    Dim webConfigStream As StreamReader = _
        File.OpenText(Path.Combine(Request.PhysicalApplicationPath, "Web.config"))
    Dim configContents As String = webConfigStream.ReadToEnd()
    webConfigStream.Close()
    WebConfigContents.Text = configContents
End Sub
```

The `DisplayWebConfig` method uses the `File` class to open the application s `Web.config` file, the `StreamReader` class to read its contents into a string, and the `Path` class to generate the physical path to the `Web.config` file. These three classes are all found in the `System.IO` namespace. Consequently, you will need to add a `Imports``System.IO` statement to the top of the code-behind class or, alternatively, prefix these class names with `System.IO.`

Next, we need to add event handlers for the two Button controls `Click` events and add the necessary code to encrypt and decrypt the `<connectionStrings>` section using a machine-level key with the DPAPI provider. From the Designer, double-click each of the Buttons to add a `Click` event handler in the code-behind class and then add the following code:

```
Protected Sub EncryptConnStrings_Click(sender As Object, e As EventArgs) _
    Handles EncryptConnStrings.Click
    'Get configuration information about Web.config
    Dim config As Configuration = _
        WebConfigurationManager.OpenWebConfiguration(Request.ApplicationPath)
    ' Let's work with the <connectionStrings> section
    Dim connectionStrings As ConfigurationSection = _
        config.GetSection("connectionStrings")
    If connectionStrings IsNot Nothing Then
        ' Only encrypt the section if it is not already protected
        If Not connectionStrings.SectionInformation.IsProtected Then
            ' Encrypt the <connectionStrings> section using the
            ' DataProtectionConfigurationProvider provider
            connectionStrings.SectionInformation.ProtectSection( _
                "DataProtectionConfigurationProvider")
            config.Save()
            ' Refresh the Web.config display
            DisplayWebConfig()
        End If
    End If
End Sub
Protected Sub DecryptConnStrings_Click(sender As Object, e As EventArgs) _
    Handles DecryptConnStrings.Click
    ' Get configuration information about Web.config
    Dim config As Configuration = _
        WebConfigurationManager.OpenWebConfiguration(Request.ApplicationPath)
    ' Let's work with the <connectionStrings> section
    Dim connectionStrings As ConfigurationSection = _
        config.GetSection("connectionStrings")
    If connectionStrings IsNot Nothing Then
        ' Only decrypt the section if it is protected
        If connectionStrings.SectionInformation.IsProtected Then
            ' Decrypt the <connectionStrings> section
            connectionStrings.SectionInformation.UnprotectSection()
            config.Save()
            ' Refresh the Web.config display
            DisplayWebConfig()
        End If
    End If
End Sub
```

The code used in the two event handlers is nearly identical. They both start by getting information about the current application s `Web.config` file via the `WebConfigurationManager` class s `OpenWebConfiguration` method. This method returns the web configuration file for the specified virtual path. Next, the `Web.config` file s `<connectionStrings>` section is accessed via the `Configuration` class s `GetSection(sectionName)` method, which returns a `ConfigurationSection` object.

The `ConfigurationSection` object includes a `SectionInformation` property that provides additional information and functionality regarding the configuration section. As the code above shows, we can determine whether the configuration section is encrypted by checking the `SectionInformation` property s `IsProtected` property. Moreover, the section can be encrypted or decrypted via the `SectionInformation` property s `ProtectSection(provider)` and `UnprotectSection` methods.

The `ProtectSection(provider)` method accepts as input a string specifying the name of the protected configuration provider to use when encrypting. In the `EncryptConnString` Button s event handler we pass DataProtectionConfigurationProvider into the `ProtectSection(provider)` method so that the DPAPI provider is used. The `UnprotectSection` method can determine the provider that was used to encrypt the configuration section and therefore does not require any input parameters.

After calling the `ProtectSection(provider)` or `UnprotectSection` method, you must call the `Configuration` object s `Save` method to persist the changes. Once the configuration information has been encrypted or decrypted and

the changes saved, we call `DisplayWebConfig` to load the updated `Web.config` contents into the TextBox control.

Once you have entered the above code, test it by visiting the `EncryptingConfigSections.aspx` page through a browser. You should initially see a page that lists the contents of `Web.config` with the `<connectionStrings>` section displayed in plain-text (see Figure 3).

Figure 3: Add a TextBox and Two Button Web Controls to the Page (Click to view full-size image)

Now click the Encrypt Connection Strings button. If request validation is enabled, the markup posted back from the `WebConfigContents` TextBox will produce an `HttpRequestValidationException`, which displays the message, A potentially dangerous `Request.Form` value was detected from the client. Request validation, which is enabled by default in ASP.NET 2.0, prohibits postbacks that include un-encoded HTML and is designed to help prevent script-injection attacks. This check can be disabled at the page- or application-level. To turn it off for this page, set the `ValidateRequest` setting to `False` in the `@Page` directive. The `@Page` directive is found at the top of the page s declarative markup.

```
<%@ Page ValidateRequest="False" ... %>
```

For more information on request validation, its purpose, how to disable it at the page- and application-level, as well as how to HTML encode markup, see Request Validation - Preventing Script Attacks.

After disabling request validation for the page, try clicking the Encrypt Connection Strings button again. On postback, the configuration file will be accessed and its `<connectionStrings>` section encrypted using the DPAPI provider. The TextBox is then updated to display the new `Web.config` content. As Figure 4 shows, the `<connectionStrings>` information is now encrypted.

Figure 4: Clicking the Encrypt Connection Strings Button Encrypts the `<connectionString>` Section (Click to view full-size image)

The encrypted `<connectionStrings>` section generated on my computer follows, although some of the content in the `<CipherData>` element has been removed for brevity:

```
<connectionStrings
    configProtectionProvider="DataProtectionConfigurationProvider">
  <EncryptedData>
    <CipherData>
      <CipherValue>AQAAANCMnd8BFdERjHoAwE/...zChw==</CipherValue>
    </CipherData>
  </EncryptedData>
</connectionStrings>
```

NOTE

The `<connectionStrings>` element specifies the provider used to perform the encryption (`DataProtectionConfigurationProvider`). This information is used by the `UnprotectSection` method when the Decrypt Connection Strings button is clicked.

When the connection string information is accessed from `Web.config` - either by code we write, from a SqlDataSource control, or the auto-generated code from the TableAdapters in our Typed DataSets - it is automatically decrypted. In short, we do not need to add any extra code or logic to decrypt the encrypted `<connectionString>` section. To demonstrate this, visit one of the earlier tutorials at this time, such as the Simple Display tutorial from the Basic Reporting section (`~/BasicReporting/SimpleDisplay.aspx`). As Figure 5 shows, the tutorial works exactly as we would expect it, indicating that the encrypted connection string information is being automatically decrypted by the ASP.NET page.

Figure 5: The Data Access Layer Automatically Decrypts the Connection String Information (Click to view full-size image)

To revert the `<connectionStrings>` section back to its plain-text representation, click the Decrypt Connection Strings button. On postback you should see the connection strings in `Web.config` in plain-text. At this point your screen should look like it did when first visiting this page (see in Figure 3).

Step 3: Encrypting Configuration Sections Using `aspnet_regiis.exe`

The .NET Framework includes a variety of command line tools in the `$WINDOWS$\Microsoft.NET\Framework\version\` folder. In the Using SQL Cache Dependencies tutorial, for instance, we looked at using the `aspnet_regsql.exe` command line tool to add the infrastructure necessary for SQL cache dependencies. Another useful command line tool in this folder is the ASP.NET IIS Registration tool (`aspnet_regiis.exe`). As its name implies, the ASP.NET IIS Registration tool is primarily used to register an ASP.NET 2.0 application with Microsoft s professional-grade Web server, IIS. In addition to its IIS-related features, the ASP.NET IIS Registration tool can also be used to encrypt or decrypt specified configuration sections in `Web.config`.

The following statement shows the general syntax used to encrypt a configuration section with the `aspnet_regiis.exe` command line tool:

```
aspnet_regiis.exe -pef section physical_directory -prov provider
```

section is the configuration section to encrypt (like connectionStrings), the *physical_directory* is the full, physical path to the web application s root directory, and *provider* is the name of the protected configuration provider to use (such as DataProtectionConfigurationProvider). Alternatively, if the web application is registered in IIS you can enter the virtual path instead of the physical path using the following syntax:

```
aspnet_regiis.exe -pe section -app virtual_directory -prov provider
```

The following `aspnet_regiis.exe` example encrypts the `<connectionStrings>` section using the DPAPI provider with a machine-level key:

```
aspnet_regiis.exe -pef
"connectionStrings" "C:\Websites\ASPNET_Data_Tutorial_73_VB"
-prov "DataProtectionConfigurationProvider"
```

Similarly, the `aspnet_regiis.exe` command line tool can be used to decrypt configuration sections. Instead of using the `-pef` switch, use `-pdf` (or instead of `-pe`, use `-pd`). Also, note that the provider name is not necessary when decrypting.

```
aspnet_regiis.exe -pdf section physical_directory
  -- or --
aspnet_regiis.exe -pd section -app virtual_directory
```

NOTE

Since we are using the DPAPI provider, which uses keys specific to the computer, you must run `aspnet_regiis.exe` from the same machine from which the web pages are being served. For example, if you run this command line program from your local development machine and then upload the encrypted Web.config file to the production server, the production server will not be able to decrypt the connection string information since it was encrypted using keys specific to your development machine. The RSA provider does not have this limitation as it is possible to export the RSA keys to another machine.

Understanding Database Authentication Options

Before any application can issue `SELECT`, `INSERT`, `UPDATE`, or `DELETE` queries to a Microsoft SQL Server database, the database first must identify the requestor. This process is known as *authentication* and SQL Server provides two methods of authentication:

- **Windows Authentication** - the process under which the application is running is used to communicate with the database. When running an ASP.NET application through Visual Studio 2005 s ASP.NET Development Server, the ASP.NET application assumes the identity of the currently logged on user. For ASP.NET applications on Microsoft Internet Information Server (IIS), ASP.NET applications usually assume the identity of `domainName``\MachineName` or `domainName``\NETWORK SERVICE`, although this can be customized.
- **SQL Authentication** - a user ID and password values are supplied as credentials for authentication. With SQL authentication, the user ID and password are provided in the connection string.

Windows authentication is preferred over SQL authentication because it is more secure. With Windows authentication the connection string is free from a username and password and if the web server and database server reside on two different machines, the credentials are not sent over the network in plain-text. With SQL authentication, however, the authentication credentials are hard-coded in the connection string and are transmitted from the web server to the database server in plain-text.

These tutorials have used Windows authentication. You can tell what authentication mode is being used by inspecting the connection string. The connection string in `Web.config` for our tutorials has been:

```
Data Source=.\SQLEXPRESS; AttachDbFilename=|DataDirectory|\NORTHWND.MDF; Integrated Security=True; User
Instance=True
```

The Integrated Security=True and lack of a username and password indicate that Windows authentication is being used. In some connection strings the term Trusted Connection=Yes or Integrated Security=SSPI is used instead of Integrated Security=True, but all three indicate the use of Windows authentication.

The following example shows a connection string that uses SQL authentication. Note the credentials embedded within the connection string:

```
Server=serverName; Database=Northwind; uid=userID; pwd=password
```

Imagine that an attacker is able to view your application s `Web.config` file. If you use SQL authentication to connect to a database that is accessible over the Internet, the attacker can use this connection string to connect to your database through SQL Management Studio or from ASP.NET pages on their own website. To help mitigate this threat, encrypt the connection string information in `Web.config` using the protected configuration system.

> **NOTE**
> For more information on the different types of authentication available in SQL Server, see Building Secure ASP.NET Applications: Authentication, Authorization, and Secure Communication. For further connection string examples illustrating the differences between Windows and SQL authentication syntax, refer to ConnectionStrings.com.

Summary

By default, files with a `.config` extension in an ASP.NET application cannot be accessed through a browser. These types of files are not returned because they may contain sensitive information, such as database connection strings, usernames and passwords, and so on. The protected configuration system in .NET 2.0 helps further protect sensitive information by allowing specified configuration sections to be encrypted. There are two built-in protected configuration providers: one that uses the RSA algorithm and one that uses the Windows Data Protection API (DPAPI).

In this tutorial we looked at how to encrypt and decrypt configuration settings using the DPAPI provider. This can be accomplished both programmatically, as we saw in Step 2, as well as through the `aspnet_regiis.exe` command line tool, which was covered in Step 3. For more information on using user-level keys or using the RSA provider instead, see the resources in the Further Reading section.

Happy Programming!

Debugging Stored Procedures (VB)

2/20/2020 • 14 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

Visual Studio Professional and Team System editions allow you to set breakpoints and step in to stored procedures within SQL Server, making debugging stored procedures as easy as debugging application code. This tutorial demonstrates direct database debugging and application debugging of stored procedures.

Introduction

Visual Studio provides a rich debugging experience. With a few keystrokes or clicks of the mouse, it s possible to use breakpoints to stop execution of a program and examine its state and control flow. Along with debugging application code, Visual Studio offers support for debugging stored procedures from within SQL Server. Just like breakpoints can be set within the code of an ASP.NET code-behind class or Business Logic Layer class, so too can they be placed within stored procedures.

In this tutorial we will look at stepping into stored procedures from the Server Explorer within Visual Studio as well as how to set breakpoints that are hit when the stored procedure is called from the running ASP.NET application.

> **NOTE**
>
> Unfortunately, stored procedures can only be stepped into and debugged through the Professional and Team Systems versions of Visual Studio. If you are using Visual Web Developer or the standard version of Visual Studio, you are welcome to read along as we walk through the steps necessary to debug stored procedures, but you will not be able to replicate these steps on your machine.

SQL Server Debugging Concepts

Microsoft SQL Server 2005 was designed to provide integration with the Common Language Runtime (CLR), which is the runtime used by all .NET assemblies. Consequently, SQL Server 2005 supports managed database objects. That is, you can create database objects like stored procedures and User-Defined Functions (UDFs) as methods in a Visual Basic class. This enables these stored procedures and UDFs to utilize functionality in the .NET Framework and from your own custom classes. Of course, SQL Server 2005 also provides support for T-SQL database objects.

SQL Server 2005 offers debugging support for both T-SQL and managed database objects. However, these objects can only be debugged through Visual Studio 2005 Professional and Team Systems editions. In this tutorial we will examine debugging T-SQL database objects. The subsequent tutorial looks at debugging managed database objects.

The Overview of T-SQL and CLR Debugging in SQL Server 2005 blog entry from the SQL Server 2005 CLR Integration team highlights the three ways to debug SQL Server 2005 objects from Visual Studio:

- **Direct Database Debugging (DDD)** - from Server Explorer we can step into any T-SQL database object, such as stored procedures and UDFs. We will examine DDD in Step 1.
- **Application Debugging** - we can set breakpoints within a database object and then run our ASP.NET application. When the database object is executed, the breakpoint will be hit and control turned over to the

debugger. Note that with application debugging we cannot step into a database object from application code. We must explicitly set breakpoints in those stored procedures or UDFs where we want the debugger to stop. Application debugging is examined starting in Step 2.

- **Debugging from a SQL Server Project** - Visual Studio Professional and Team Systems editions include a SQL Server Project type that is commonly used to create managed database objects. We will examine using SQL Server Projects and debugging their contents in the next tutorial.

Visual Studio can debug stored procedures on local and remote SQL Server instances. A local SQL Server instance is one that is installed on the same machine as Visual Studio. If the SQL Server database you are using is not located on your development machine, then it is considered a remote instance. For these tutorials we have been using local SQL Server instances. Debugging stored procedures on a remote SQL server instance requires more configuration steps than when debugging stored procedures on a local instance.

If you are using a local SQL Server instance, you can start with Step 1 and work through this tutorial to the end. If you are using a remote SQL Server instance, however, you will first need to ensure that when debugging you are logged to your development machine with a Windows user account that has a SQL Server login on the remote instance. Moreover, both this database login and the database login used to connect to the database from the running ASP.NET application must be members of the `sysadmin` role. See the Debugging T-SQL Database Objects on Remote Instances section at the end of this tutorial for more information on configuring Visual Studio and SQL Server to debug a remote instance.

Finally, understand that debugging support for T-SQL database objects is not as feature rich as debugging support for .NET applications. For example, breakpoint conditions and filters are not supported, only a subset of the debugging windows are available, you cannot use Edit and Continue, the Immediate window is rendered useless, and so forth. See Limitations on Debugger Commands and Features for more information.

Step 1: Directly Stepping Into a Stored Procedure

Visual Studio makes it easy to directly debug a database object. Let s look at how to use the Direct Database Debugging (DDD) feature to step into the `Products_SelectByCategoryID` stored procedure in the Northwind database. As its name implies, `Products_SelectByCategoryID` returns product information for a particular category; it was created in the Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorial. Start by going to the Server Explorer and expand the Northwind database node. Next, drill down into the Stored Procedures folder, right-click on the `Products_SelectByCategoryID` stored procedure, and choose the Step Into Stored Procedure option from the context menu. This will start the debugger.

Since the `Products_SelectByCategoryID` stored procedure expects a `@CategoryID` input parameter, we are asked to provide this value. Enter 1, which will return information about the beverages.

Figure 1: Use the Value 1 for the `@CategoryID` Parameter

After supplying the value for the `@CategoryID` parameter, the stored procedure is executed. Rather than running to completion, though, the debugger halts execution on the first statement. Note the yellow arrow in the margin, indicating the current location in the stored procedure. You can view and edit parameter values through the Watch window or by hovering over the parameter name in the stored procedure.

Figure 2: The Debugger has Halted on the First Statement of the Stored Procedure (Click to view full-size image)

To step through the stored procedure one statement at a time, click the Step Over button in the Toolbar or hit the F10 key. The `Products_SelectByCategoryID` stored procedure contains a single `SELECT` statement, so hitting F10 will step over the single statement and complete the execution of the stored procedure. After the stored procedure has completed, its output will appear in the Output window and the debugger will terminate.

> **NOTE**
>
> T-SQL debugging occurs at the statement level; you cannot step into a `SELECT` statement.

Step 2: Configuring the Website for Application Debugging

While debugging a stored procedure directly from the Server Explorer is handy, in many scenarios we are more interested in debugging the stored procedure when it is called from our ASP.NET application. We can add breakpoints to a stored procedure from within Visual Studio and then start debugging the ASP.NET application. When a stored procedure with breakpoints is invoked from the application, execution will halt at the breakpoint and we can view and change the stored procedure s parameter values and step through its statements, just like we did in Step 1.

Before we can start debugging stored procedures called from the application, we need to instruct the ASP.NET web application to integrate with the SQL Server debugger. Start by right-clicking on the website name in the Solution Explorer (`ASPNET_Data_Tutorial_74_VB`). Choose the Property Pages option from the context menu, select the Start Options item on the left, and check the SQL Server checkbox in the Debuggers section (see Figure 3).

Figure 3: Check the SQL Server Checkbox in the Application s Property Pages (Click to view full-size image)

Additionally, we need to update the database connection string used by the application so that connection pooling is disabled. When a connection to a database is closed, the corresponding `SqlConnection` object is placed in a pool of available connections. When establishing a connection to a database, an available connection object can be retrieved from this pool rather than having to create and establish a new connection. This pooling of connection objects is a performance enhancement and is enabled by default. However, when debugging we want to turn off connection pooling because the debugging infrastructure is not correctly reestablished when working with a connection that was taken from the pool.

To disabled connection pooling, update the `NORTHWNDConnectionString` in `Web.config` so that it includes the setting `Pooling=false` .

```
<connectionStrings>
    <add name="NORTHWNDConnectionString" connectionString=
        "Data Source=.\SQLEXPRESS;AttachDbFilename=|DataDirectory|\NORTHWND.MDF;
            Integrated Security=True;User Instance=True;Pooling=false"
        providerName="System.Data.SqlClient" />
</connectionStrings>
```

NOTE

Once you have finished debugging SQL Server through the ASP.NET application be sure to reinstate connection pooling by removing the `Pooling` setting from the connection string (or by setting it to `Pooling=true`).

At this point the ASP.NET application has been configured to allow Visual Studio to debug SQL Server database objects when invoked through the web application. All that remains now is to add a breakpoint to a stored procedure and start debugging!

Step 3: Adding a Breakpoint and Debugging

Open the `Products_SelectByCategoryID` stored procedure and set a breakpoint at the start of the `SELECT` statement by clicking in the margin at the appropriate place or by placing your cursor at the start of the `SELECT` statement and hitting F9. As Figure 4 illustrates, the breakpoint appears as a red circle in the margin.

Figure 4: Set a Breakpoint in the `Products_SelectByCategoryID` Stored Procedure (Click to view full-size image)

In order for a SQL database object to be debugged through a client application, it is imperative that the database be configured to support application debugging. When you first set a breakpoint, this setting should automatically be switched on, but it is prudent to double-check. Right-click on the `NORTHWND.MDF` node in the Server Explorer. The context menu should include a checked menu item named Application Debugging .

Figure 5: Ensure that the Application Debugging Option is Enabled

With the breakpoint set and the Application Debugging option enabled, we are ready to debug the stored procedure when called from the ASP.NET application. Start the debugger by going to the Debug menu and choosing Start Debugging, by hitting F5, or by clicking the green play icon in the Toolbar. This will start the debugger and launch the website.

The `Products_SelectByCategoryID` stored procedure was created in the Using Existing Stored Procedures for the Typed DataSet s TableAdapters tutorial. Its corresponding web page (`~/AdvancedDAL/ExistingSprocs.aspx`) contains a GridView that displays the results returned by this stored procedure. Visit this page through the browser. Upon reaching the page, the breakpoint in the `Products_SelectByCategoryID` stored procedure will be hit and control returned to Visual Studio. Just like in Step 1, you can step through the stored procedure s statements and view and modify the parameter values.

Figure 6: The `ExistingSprocs.aspx` Page Initially Displays the Beverages (Click to view full-size image)

Figure 7: The Stored Procedure s Breakpoint has been Reached (Click to view full-size image)

As the Watch window in Figure 7 shows, the value of the `@CategoryID` parameter is 1. This is because the `ExistingSprocs.aspx` page initially displays products in the beverages category, which has a `CategoryID` value of 1. Choose a different category from the drop-down list. Doing so causes a postback and re-executes the `Products_SelectByCategoryID` stored procedure. The breakpoint is hit again, but this time the `@CategoryID` parameter s value reflects the selected drop-down list item s `CategoryID`.

Figure 8: Choose a Different Category from the Drop-Down List (Click to view full-size image)

Figure 9: The `@CategoryID` Parameter Reflects the Category Selected from the Web Page (Click to view full-size image)

> **NOTE**
>
> If the breakpoint in the `Products_SelectByCategoryID` stored procedure is not hit when visiting the `ExistingSprocs.aspx` page, make sure that the SQL Server checkbox has been checked in the Debuggers section of the ASP.NET application s Properties Page, that connection pooling has been disabled, and that the database s Application Debugging option is enabled. If you re still having problems, restart Visual Studio and try again.

Debugging T-SQL Database Objects on Remote Instances

Debugging database objects through Visual Studio is fairly straightforward when the SQL Server database instance is on the same machine as Visual Studio. However, if SQL Server and Visual Studio reside on different machines then some careful configuration is required to get everything working properly. There are two core tasks we are faced with:

- Ensure that the login used to connect to the database via ADO.NET belongs to the `sysadmin` role.
- Ensure that the Windows user account used by Visual Studio on the development machine is a valid SQL

Server login account that belongs to the `sysadmin` role.

The first step is relatively straightforward. First, identify the user account used to connect to the database from the ASP.NET application and then, from SQL Server Management Studio, add that login account to the `sysadmin` role.

The second task requires that the Windows user account you use to debug the application be a valid login on the remote database. However, chances are the Windows account you logged on to your workstation with is not a valid login on SQL Server. Rather than adding your particular login account to SQL Server, a better choice would be to designate some Windows user account as the SQL Server debugging account. Then, to debug the database objects of a remote SQL Server instance, you would run Visual Studio using that Windows login account s credentials.

An example should help clarify things. Imagine that there is a Windows account named `SQLDebug` within the Windows domain. This account would need to be added to the remote SQL Server instance as a valid login and as a member of the `sysadmin` role. Then, to debug the remote SQL Server instance from Visual Studio, we would need to run Visual Studio as the `SQLDebug` user. This could be done by logging out of our workstation, logging back in as `SQLDebug`, and then launching Visual Studio, but a simpler approach would be to login to our workstation using our own credentials and then use `runas.exe` to launch Visual Studio as the `SQLDebug` user. `runas.exe` allows a particular application to be executed under the guise of a different user account. To launch Visual Studio as `SQLDebug`, you could enter the following statement at the command line:

```
runas.exe /user:SQLDebug "%PROGRAMFILES%\Microsoft Visual Studio 8\Common7\IDE\devenv.exe"
```

For a more detailed explanation on this process, see William R. Vaughn s *Hitchhiker s Guide to Visual Studio and SQL Server, Seventh Edition* as well as How To: Set SQL Server Permissions for Debugging.

> **NOTE**
> If your development machine is running Windows XP Service Pack 2 you will need to configure the Internet Connection Firewall to allow remote debugging. The How To: Enable SQL Server 2005 Debugging article notes that this involves two steps: (a) On the Visual Studio host machine, you must add `Devenv.exe` to the Exceptions list and open the TCP 135 port; and (b) On the remote (SQL) machine, you must open the TCP 135 port and add `sqlservr.exe` to the Exceptions list. If your domain policy requires network communication to be done through IPSec, you must open the UDP 4500 and UDP 500 ports.

Summary

In addition to providing debugging support for .NET application code, Visual Studio also provides a variety of debugging options for SQL Server 2005. In this tutorial we looked at two of those options: Direct Database Debugging and application debugging. To directly debug a T-SQL database object, locate the object through the Server Explorer then right-click on it and choose Step Into. This starts the debugger and halts on the first statement in the database object, at which point you can step through the object s statements and view and modify parameter values. In Step 1 we used this approach to step into the `Products_SelectByCategoryID` stored procedure.

Application debugging allows breakpoints to be set directly within the database objects. When a database object with breakpoints is invoked from a client application (such as an ASP.NET web application), the program halts as the debugger takes over. Application debugging is useful because it more clearly shows what application action causes a particular database object to be invoked. However, it requires a bit more configuration and setup than Direct Database Debugging.

Database objects can also be debugged through SQL Server Projects. We will look at using SQL Server Projects

and how to use them to create and debug managed database objects in the next tutorial.

Creating Stored Procedures and User-Defined Functions with Managed Code (VB)

9/16/2020 • 36 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

Microsoft SQL Server 2005 integrates with the .NET Common Language Runtime to allow developers to create database objects through managed code. This tutorial shows how to create managed stored procedures and managed user-defined functions with your Visual Basic or C# code. We also see how these editions of Visual Studio allow you to debug such managed database objects.

Introduction

Databases like Microsoft s SQL Server 2005 use the Transact-Structured Query Language (T-SQL) for inserting, modifying, and retrieving data. Most database systems include constructs for grouping a series of SQL statements that can then be executed as a single, reusable unit. Stored procedures are one example. Another is *User-Defined Functions*(UDFs), a construct that we will examine in greater detail in Step 9.

At its core, SQL is designed for working with sets of data. The `SELECT`, `UPDATE`, and `DELETE` statements inherently apply to all records in the corresponding table and are only limited by their `WHERE` clauses. Yet there are many language features designed for working with one record at a time and for manipulating scalar data. `CURSOR` s allow for a set of records to be looped through one at a time. String manipulation functions like `LEFT`, `CHARINDEX`, and `PATINDEX` work with scalar data. SQL also includes control flow statements like `IF` and `WHILE`.

Prior to Microsoft SQL Server 2005, stored procedures and UDFs could only be defined as a collection of T-SQL statements. SQL Server 2005, however, was designed to provide integration with the Common Language Runtime (CLR), which is the runtime used by all .NET assemblies. Consequently, the stored procedures and UDFs in a SQL Server 2005 database can be created using managed code. That is, you can create a stored procedure or UDF as a method in a Visual Basic class. This enables these stored procedures and UDFs to utilize functionality in the .NET Framework and from your own custom classes.

In this tutorial we will examine how to create managed stored procedures and User-Defined Functions and how to integrate them into our Northwind database. Let s get started!

> **NOTE**
> Managed database objects offer some advantages over their SQL counterparts. Language richness and familiarity and the ability to reuse existing code and logic are the main advantages. But managed database objects are likely to be less efficient when working with sets of data that do not involve much procedural logic. For a more thorough discussion on the advantages of using managed code versus T-SQL, check out the Advantages of Using Managed Code to Create Database Objects.

Step 1: Moving the Northwind Database Out of `App_Data`

All of our tutorials thus far have used a Microsoft SQL Server 2005 Express Edition database file in the web application s `App_Data` folder. Placing the database in `App_Data` simplified distributing and running these tutorials as all of the files were located within one directory and required no additional configuration steps to test the

tutorial.

For this tutorial, however, let s move the Northwind database out of `App_Data` and explicitly register it with the SQL Server 2005 Express Edition database instance. While we can perform the steps for this tutorial with the database in the `App_Data` folder, a number of the steps are made much simpler by explicitly registering the database with the SQL Server 2005 Express Edition database instance.

The download for this tutorial has the two database files - `NORTHWND.MDF` and `NORTHWND_log.LDF` - placed in a folder named `DataFiles`. If you are following along with your own implementation of the tutorials, close Visual Studio and move the `NORTHWND.MDF` and `NORTHWND_log.LDF` files from the website s `App_Data` folder to a folder outside of the website. Once the database files have been moved to another folder we need to register the Northwind database with the SQL Server 2005 Express Edition database instance. This can be done from SQL Server Management Studio. If you have a non-Express Edition of SQL Server 2005 installed on your computer then you likely already have Management Studio installed. If you only have SQL Server 2005 Express Edition on your computer then take a moment to download and install Microsoft SQL Server Management Studio Express.

Launch SQL Server Management Studio. As Figure 1 shows, Management Studio starts by asking what server to connect to. Enter localhost\SQLExpress for the server name, choose Windows Authentication in the Authentication drop-down list, and click Connect.

Figure 1: Connect to the Appropriate Database Instance

Once you ve connected, the Object Explorer window will list information about the SQL Server 2005 Express Edition database instance, including its databases, security information, management options, and so forth.

We need to attach the Northwind database in the `DataFiles` folder (or wherever you may have moved it) to the SQL Server 2005 Express Edition database instance. Right-click on the Databases folder and choose the Attach option from the context menu. This will bring up the Attach Databases dialog box. Click the Add button, drill down to the appropriate `NORTHWND.MDF` file, and click OK. At this point your screen should look similar to Figure 2.

Figure 2: Connect to the Appropriate Database Instance (Click to view full-size image)

> **NOTE**
>
> When connecting to the SQL Server 2005 Express Edition instance through Management Studio the Attach Databases dialog box does not allow you to drill down into user profile directories, such as My Documents. Therefore, make sure to place the `NORTHWND.MDF` and `NORTHWND_log.LDF` files in a non-user profile directory.

Click the OK button to attach the database. The Attach Databases dialog box will close and the Object Explorer should now list the just-attached database. Chances are the Northwind database has a name like

```
9FE54661B32FDD967F51D71D0D5145CC_LINE ARTICLES\DATATUTORIALS\VOLUME
3\CSHARP\73\ASPNET_DATA_TUTORIAL_75_CS\APP_DATA\NORTHWND.MDF
```

. Rename the database to Northwind by right-clicking on the database and choosing Rename.

Figure 3: Rename the Database to Northwind

Step 2: Creating a New Solution and SQL Server Project in Visual Studio

To create managed stored procedures or UDFs in SQL Server 2005 we will write the stored procedure and UDF logic as Visual Basic code in a class. Once the code has been written, we will need to compile this class into an assembly (a `.dll` file), register the assembly with the SQL Server database, and then create a stored procedure or UDF object in the database that points to the corresponding method in the assembly. These steps can all be performed manually. We can create the code in any text editor, compile it from the command line using the Visual Basic compiler (`vbc.exe`), register it with the database using the `CREATE ASSEMBLY` command or from Management Studio, and add the stored procedure or UDF object through similar means. Fortunately, the Professional and Team Systems versions of Visual Studio include a SQL Server Project type that automates these tasks. In this tutorial we will walk through using the SQL Server Project type to create a managed stored procedure and UDF.

> **NOTE**
>
> If you are using Visual Web Developer or the Standard edition of Visual Studio, then you will have to use the manual approach instead. Step 13 provides detailed instructions for performing these steps manually. I encourage you to read Steps 2 through 12 before reading Step 13 since these steps include important SQL Server configuration instructions that must be applied regardless of what version of Visual Studio you are using.

Start by opening Visual Studio. From the File menu, choose New Project to display the New Project dialog box (see Figure 4). Drill down to the Database project type and then, from the Templates listed on the right, choose to create a new SQL Server Project. I have chosen to name this project `ManagedDatabaseConstructs` and placed it within a Solution named `Tutorial75`.

Figure 4: Create a New SQL Server Project (Click to view full-size image)

Click the OK button in the New Project dialog box to create the Solution and SQL Server Project.

A SQL Server Project is tied to a particular database. Consequently, after creating the new SQL Server Project we are immediately asked to specify this information. Figure 5 shows the New Database Reference dialog box that has been filled out to point to the Northwind database we registered in the SQL Server 2005 Express Edition database instance back in Step 1.

Figure 5: Associate the SQL Server Project with the Northwind Database

In order to debug the managed stored procedures and UDFs we will create within this project, we need to enable SQL/CLR debugging support for the connection. Whenever associating a SQL Server Project with a new database (as we did in Figure 5), Visual Studio asks us if we want to enable SQL/CLR debugging on the connection (see Figure 6). Click Yes.

Figure 6: Enable SQL/CLR Debugging

At this point the new SQL Server Project has been added to the Solution. It contains a folder named `Test Scripts` with a file named `Test.sql`, which is used for debugging the managed database objects created in the project. We will look at debugging in Step 12.

We can now add new managed stored procedures and UDFs to this project, but before we do let s first include our existing web application in the Solution. From the File menu select the Add option and choose Existing Web Site. Browse to the appropriate website folder and click OK. As Figure 7 shows, this will update the Solution to include two projects: the website and the `ManagedDatabaseConstructs` SQL Server Project.

Figure 7: The Solution Explorer Now Includes Two Projects

The `NORTHWNDConnectionString` value in `Web.config` currently references the `NORTHWND.MDF` file in the `App_Data` folder. Since we removed this database from `App_Data` and explicitly registered it in the SQL Server 2005 Express Edition database instance, we need to correspondingly update the `NORTHWNDConnectionString` value. Open the `Web.config` file in the website and change the `NORTHWNDConnectionString` value so that the connection string reads: `Data Source=localhost\SQLExpress;Initial Catalog=Northwind;Integrated Security=True`. After this change, your `<connectionStrings>` section in `Web.config` should look similar to the following:

```
<connectionStrings>
    <add name="NORTHWNDConnectionString" connectionString=
        "Data Source=localhost\SQLExpress;Initial Catalog=Northwind;
            Integrated Security=True;Pooling=false"
        providerName="System.Data.SqlClient" />
</connectionStrings>
```

NOTE

As discussed in the preceding tutorial, when debugging a SQL Server object from a client application, such as an ASP.NET website, we need to disable connection pooling. The connection string shown above disables connection pooling (`Pooling=false`). If you do not plan on debugging the managed stored procedures and UDFs from the ASP.NET website, enable connection pooling.

Step 3: Creating a Managed Stored Procedure

To add a managed stored procedure to the Northwind database we first need to create the stored procedure as a method in the SQL Server Project. From the Solution Explorer, right-click on the `ManagedDatabaseConstructs` project name and choose to add a new item. This will display the Add New Item dialog box, which lists the types of managed database objects that can be added to the project. As Figure 8 shows, this includes stored procedures and User-Defined Functions, among others.

Let s start by adding a stored procedure that simply returns all of the products that have been discontinued. Name the new stored procedure file `GetDiscontinuedProducts.vb`.

Figure 8: Add a New Stored Procedure Named `GetDiscontinuedProducts.vb` (Click to view full-size image)

This will create a new Visual Basic class file with the following content:

```
Imports System
Imports System.Data
Imports System.Data.SqlClient
Imports System.Data.SqlTypes
Imports Microsoft.SqlServer.Server
Partial Public Class StoredProcedures
    <Microsoft.SqlServer.Server.SqlProcedure()> _
    Public Shared Sub  GetDiscontinuedProducts ()
        ' Add your code here
    End Sub
End Class
```

Note that the stored procedure is implemented as a `Shared` method within a `Partial` class file named `StoredProcedures`. Moreover, the `GetDiscontinuedProducts` method is decorated with the `SqlProcedure` attribute, which marks the method as a stored procedure.

The following code creates a `SqlCommand` object and sets its `CommandText` to a `SELECT` query that returns all of the columns from the `Products` table for products whose `Discontinued` field equals 1. It then executes the command and sends the results back to the client application. Add this code to the `GetDiscontinuedProducts` method.

```
' Create the command
Dim myCommand As New SqlCommand()
myCommand.CommandText = _
    "SELECT ProductID, ProductName, SupplierID, CategoryID, " & _
    "       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder, " & _
    "       ReorderLevel, Discontinued " & _
    "FROM Products " & _
    "WHERE Discontinued = 1"
' Execute the command and send back the results
SqlContext.Pipe.ExecuteAndSend(myCommand)
```

All managed database objects have access to a `SqlContext` object that represents the context of the caller. The `SqlContext` provides access to a `SqlPipe` object via its `Pipe` property. This `SqlPipe` object is used to ferry information between the SQL Server database and the calling application. As its name implies, the `ExecuteAndSend` method executes a passed-in `SqlCommand` object and sends the results back to the client application.

> **NOTE**
> Managed database objects are best suited for stored procedures and UDFs that use procedural logic rather than set-based logic. Procedural logic involves working with sets of data on a row-by-row basis or working with scalar data. The `GetDiscontinuedProducts` method we just created, however, involves no procedural logic. Therefore, it would ideally be implemented as a T-SQL stored procedure. It is implemented as a managed stored procedure to demonstrate the steps necessary for creating and deploying managed stored procedures.

Step 4: Deploying the Managed Stored Procedure

With this code complete, we are ready to deploy it to the Northwind database. Deploying a SQL Server Project compiles the code into an assembly, registers the assembly with the database, and creates the corresponding objects in the database, linking them to the appropriate methods in the assembly. The exact set of tasks performed by the Deploy option is more precisely spelled out in Step 13. Right-click on the `ManagedDatabaseConstructs` project name in the Solution Explorer and choose the Deploy option. However, deployment fails with the following error: Incorrect syntax near 'EXTERNAL'. You may need to set the compatibility level of the current database to a higher value to enable this feature. See help for the stored procedure `sp_dbcmptlevel`.

This error message occurs when attempting to register the assembly with the Northwind database. In order to register an assembly with a SQL Server 2005 database, the database s compatibility level must be set to 90. By default, new SQL Server 2005 databases have a compatibility level of 90. However, databases created using Microsoft SQL Server 2000 have a default compatibility level of 80. Since the Northwind database was initially a Microsoft SQL Server 2000 database, its compatibility level is currently set to 80 and therefore needs to be increased to 90 in order to register managed database objects.

To update the database s compatibility level, open a New Query window in Management Studio and enter:

```
exec sp_dbcmptlevel 'Northwind', 90
```

Click the Execute icon in the Toolbar to run the above query.

Figure 9: Update the Northwind Database s Compatibility Level (Click to view full-size image)

After updating the compatibility level, redeploy the SQL Server Project. This time the deployment should complete without error.

Return to SQL Server Management Studio, right-click on the Northwind database in the Object Explorer, and choose Refresh. Next, drill down into the Programmability folder and then expand the Assemblies folder. As Figure 10 shows, the Northwind database now includes the assembly generated by the `ManagedDatabaseConstructs` project.

Figure 10: The `ManagedDatabaseConstructs` Assembly is Now Registered with the Northwind Database

Also expand the Stored Procedures folder. There you will see a stored procedure named `GetDiscontinuedProducts`. This stored procedure was created by the deployment process and points to the `GetDiscontinuedProducts` method in the `ManagedDatabaseConstructs` assembly. When the `GetDiscontinuedProducts` stored procedure is executed, it, in turn, executes the `GetDiscontinuedProducts` method. Since this is a managed stored procedure it cannot be edited

through Management Studio (hence the lock icon next to the stored procedure name).

Figure 11: The `GetDiscontinuedProducts` Stored Procedure is Listed in the Stored Procedures Folder

There is still one more hurdle we have to overcome before we can call the managed stored procedure: the database is configured to prevent execution of managed code. Verify this by opening a new query window and executing the `GetDiscontinuedProducts` stored procedure. You will receive the following error message: Execution of user code in the .NET Framework is disabled. Enable 'clr enabled configuration option.

To examine the Northwind database s configuration information, enter and execute the command `exec sp_configure` in the query window. This shows that the clr enabled setting is currently set to 0.

Figure 12: The clr enabled Setting is Currently Set to 0 (Click to view full-size image)

Note that each configuration setting in Figure 12 has four values listed with it: the minimum and maximum values

and the config and run values. To update the config value for the clr enabled setting, execute the following command:

```
exec sp_configure 'clr enabled', 1
```

If you re-run the `exec sp_configure` you will see that the above statement updated the clr enabled setting s config value to 1, but that the run value is still set to 0. For this configuration change to take affect we need to execute the `RECONFIGURE` command, which will set the run value to the current config value. Simply enter `RECONFIGURE` in the query window and click the Execute icon in the Toolbar. If you run `exec sp_configure` now you should see a value of 1 for the clr enabled setting s config and run values.

With the clr enabled configuration complete, we are ready to run the managed `GetDiscontinuedProducts` stored procedure. In the query window enter and execute the command `exec` `GetDiscontinuedProducts`. Invoking the stored procedure causes the corresponding managed code in the `GetDiscontinuedProducts` method to execute. This code issues a `SELECT` query to return all products that are discontinued and returns this data to the calling application, which is SQL Server Management Studio in this instance. Management Studio receives these results and displays them in the Results window.

Figure 13: The `GetDiscontinuedProducts` Stored Procedure Returns All Discontinued Products (Click to view full-size image)

Step 5: Creating Managed Stored Procedures that Accept Input Parameters

Many of the queries and stored procedures we have created throughout these tutorials have used *parameters*. For example, in the Creating New Stored Procedures for the Typed DataSet s TableAdapters tutorial we created a stored procedure named `GetProductsByCategoryID` that accepted an input parameter named `@CategoryID`. The stored procedure then returned all products whose `CategoryID` field matched the value of the supplied `@CategoryID` parameter.

To create a managed stored procedure that accepts input parameters, simply specify those parameters in the method s definition. To illustrate this, let s add another managed stored procedure to the `ManagedDatabaseConstructs` project named `GetProductsWithPriceLessThan`. This managed stored procedure will accept an input parameter specifying a price and will return all products whose `UnitPrice` field is less than the parameter s value.

To add a new stored procedure to the project, right-click on the `ManagedDatabaseConstructs` project name and choose to add a new stored procedure. Name the file `GetProductsWithPriceLessThan.vb`. As we saw in Step 3, this will create a new Visual Basic class file with a method named `GetProductsWithPriceLessThan` placed within the `Partial` class `StoredProcedures`.

Update the `GetProductsWithPriceLessThan` method s definition so that it accepts a `SqlMoney` input parameter

named `price` and write the code to execute and return the query results:

```
<Microsoft.SqlServer.Server.SqlProcedure()> _
Public Shared Sub GetProductsWithPriceLessThan(ByVal price As SqlMoney)
    'Create the command
    Dim myCommand As New SqlCommand()
    myCommand.CommandText = _
        "SELECT ProductID, ProductName, SupplierID, CategoryID, " & _
        "       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder, " & _
        "       ReorderLevel, Discontinued " & _
        "FROM Products " & _
        "WHERE UnitPrice < @MaxPrice"
    myCommand.Parameters.AddWithValue("@MaxPrice", price)
    ' Execute the command and send back the results
    SqlContext.Pipe.ExecuteAndSend(myCommand)
End Sub
```

The `GetProductsWithPriceLessThan` method s definition and code closely resembles the definition and code of the `GetDiscontinuedProducts` method created in Step 3. The only differences are that the `GetProductsWithPriceLessThan` method accepts as input parameter (`price`), the `SqlCommand` s query includes a parameter (`@MaxPrice`), and a parameter is added to the `SqlCommand` s `Parameters` collection is and assigned the value of the `price` variable.

After adding this code, redeploy the SQL Server Project. Next, return to SQL Server Management Studio and Refresh the Stored Procedures folder. You should see a new entry, `GetProductsWithPriceLessThan`. From a query window, enter and execute the command `exec GetProductsWithPriceLessThan 25`, which will list all products less than $25, as Figure 14 shows.

Figure 14: Products Under $25 are Displayed (Click to view full-size image)

Step 6: Calling the Managed Stored Procedure from the Data Access Layer

At this point we have added the `GetDiscontinuedProducts` and `GetProductsWithPriceLessThan` managed stored procedures to the `ManagedDatabaseConstructs` project and have registered them with the Northwind SQL Server database. We also invoked these managed stored procedures from SQL Server Management Studio (see Figures 13 and 14). In order for our ASP.NET application to use these managed stored procedures, however, we need to add them to the Data Access and Business Logic Layers in the architecture. In this step we will add two new methods to the `ProductsTableAdapter` in the `NorthwindWithSprocs` Typed DataSet, which was initially created in the Creating New Stored Procedures for the Typed DataSet s TableAdapters tutorial. In Step 7 we will add corresponding methods to the BLL.

Open the `NorthwindWithSprocs` Typed DataSet in Visual Studio and start by adding a new method to the `ProductsTableAdapter` named `GetDiscontinuedProducts`. To add a new method to a TableAdapter, right-click on the TableAdapter s name in the Designer and choose the Add Query option from the context menu.

> **NOTE**
>
> Since we moved the Northwind database from the `App_Data` folder to the SQL Server 2005 Express Edition database instance, it is imperative that the corresponding connection string in Web.config be updated to reflect this change. In Step 2 we discussed updating the `NORTHWNDConnectionString` value in `Web.config`. If you forgot to make this update, then you will see the error message Failed to add query. Unable to find connection `NORTHWNDConnectionString` for object `Web.config` in a dialog box when attempting to add a new method to the TableAdapter. To resolve this error, click OK and then go to `Web.config` and update the `NORTHWNDConnectionString` value as discussed in Step 2. Then try re-adding the method to the TableAdapter. This time it should work without error.

Adding a new method launches the TableAdapter Query Configuration wizard, which we have used many times in past tutorials. The first step asks us to specify how the TableAdapter should access the database: through an ad-hoc SQL statement or via a new or existing stored procedure. Since we have already created and registered the `GetDiscontinuedProducts` managed stored procedure with the database, choose the Use existing stored procedure option and hit Next.

Figure 15: Choose the Use existing stored procedure Option (Click to view full-size image)

The next screen prompts us for the stored procedure the method will invoke. Choose the `GetDiscontinuedProducts` managed stored procedure from the drop-down list and hit Next.

Figure 16: Select the `GetDiscontinuedProducts` Managed Stored Procedure (Click to view full-size image)

We are then asked to specify whether the stored procedure returns rows, a single value, or nothing. Since `GetDiscontinuedProducts` returns the set of discontinued product rows, choose the first option (Tabular data) and click Next.

Figure 17: Select the Tabular Data Option (Click to view full-size image)

The final wizard screen allows us to specify the data access patterns used and the names of the resulting methods. Leave both checkboxes checked and name the methods `FillByDiscontinued` and `GetDiscontinuedProducts`. Click Finish to complete the wizard.

Figure 18: Name the Methods `FillByDiscontinued` and `GetDiscontinuedProducts` (Click to view full-size image)

Repeat these steps to create methods named `FillByPriceLessThan` and `GetProductsWithPriceLessThan` in the `ProductsTableAdapter` for the `GetProductsWithPriceLessThan` managed stored procedure.

Figure 19 shows a screenshot of the DataSet Designer after adding the methods to the `ProductsTableAdapter` for the `GetDiscontinuedProducts` and `GetProductsWithPriceLessThan` managed stored procedures.

Figure 19: The `ProductsTableAdapter` Includes the New Methods Added in this Step (Click to view full-size image)

Step 7: Adding Corresponding Methods to the Business Logic Layer

Now that we have updated the Data Access Layer to include methods for calling the managed stored procedures added in Steps 4 and 5, we need to add corresponding methods to the Business Logic Layer. Add the following two methods to the `ProductsBLLWithSprocs` class:

```
<System.ComponentModel.DataObjectMethodAttribute _
    (System.ComponentModel.DataObjectMethodType.Select, False)> _
Public Function GetDiscontinuedProducts() As NorthwindWithSprocs.ProductsDataTable
    Return Adapter.GetDiscontinuedProducts()
End Function
<System.ComponentModel.DataObjectMethodAttribute _
    (System.ComponentModel.DataObjectMethodType.Select, False)> _
Public Function GetProductsWithPriceLessThan(ByVal priceLessThan As Decimal) _
    As NorthwindWithSprocs.ProductsDataTable
    Return Adapter.GetProductsWithPriceLessThan(priceLessThan)
End Function
```

Both methods simply call the corresponding DAL method and return the `ProductsDataTable` instance. The `DataObjectMethodAttribute` markup above each method causes these methods to be included in the drop-down list in the SELECT tab of the ObjectDataSource s Configure Data Source wizard.

Step 8: Invoking the Managed Stored Procedures from the Presentation Layer

With the Business Logic and Data Access Layers augmented to include support for calling the `GetDiscontinuedProducts` and `GetProductsWithPriceLessThan` managed stored procedures, we can now display these stored procedures results through an ASP.NET page.

Open the `ManagedFunctionsAndSprocs.aspx` page in the `AdvancedDAL` folder and, from the Toolbox, drag a GridView onto the Designer. Set the GridView s `ID` property to `DiscontinuedProducts` and, from its smart tag, bind it to a new ObjectDataSource named `DiscontinuedProductsDataSource`. Configure the ObjectDataSource to pull its data from the `ProductsBLLWithSprocs` class s `GetDiscontinuedProducts` method.

Figure 20: Configure the ObjectDataSource to Use the `ProductsBLLWithSprocs` Class (Click to view full-size image)

Figure 21: Choose the `GetDiscontinuedProducts` Method from the Drop-Down List in the SELECT Tab (Click to view full-size image)

Since this grid will be used to just display product information, set the drop-down lists in the UPDATE, INSERT, and DELETE tabs to (None) and then click Finish.

Upon completing the wizard, Visual Studio will automatically add a BoundField or CheckBoxField for each data field in the `ProductsDataTable`. Take a moment to remove all of these fields except for `ProductName` and `Discontinued`, at which point your GridView and ObjectDataSource s declarative markup should look similar to the following:

```
<asp:GridView ID="DiscontinuedProducts" runat="server"
    AutoGenerateColumns="False" DataKeyNames="ProductID"
    DataSourceID="DiscontinuedProductsDataSource">
    <Columns>
        <asp:BoundField DataField="ProductName" HeaderText="ProductName"
            SortExpression="ProductName" />
        <asp:CheckBoxField DataField="Discontinued"
            HeaderText="Discontinued"
            SortExpression="Discontinued" />
    </Columns>
</asp:GridView>
<asp:ObjectDataSource ID="DiscontinuedProductsDataSource" runat="server"
    OldValuesParameterFormatString="original_{0}"
    SelectMethod="GetDiscontinuedProducts" TypeName="ProductsBLLWithSprocs">
</asp:ObjectDataSource>
```

Take a moment to view this page through a browser. When the page is visited, the ObjectDataSource calls the `ProductsBLLWithSprocs` class s `GetDiscontinuedProducts` method. As we saw in Step 7, this method calls down to the DAL s `ProductsDataTable` class s `GetDiscontinuedProducts` method, which invokes the `GetDiscontinuedProducts` stored procedure. This stored procedure is a managed stored procedure and executes the code we created in Step 3, returning the discontinued products.

The results returned by the managed stored procedure are packaged up into a `ProductsDataTable` by the DAL and then returned to the BLL, which then returns them to the Presentation Layer where they are bound to the GridView and displayed. As expected, the grid lists those products that have been discontinued.

Figure 22: The Discontinued Products are Listed (Click to view full-size image)

For further practice, add a TextBox and another GridView to the page. Have this GridView display the products less than the amount entered into the TextBox by calling the `ProductsBLLWithSprocs` class s `GetProductsWithPriceLessThan` method.

Step 9: Creating and Calling T-SQL UDFs

User-Defined Functions, or UDFs, are database objects the closely mimic the semantics of functions in programming languages. Like a function in Visual Basic, UDFs can include a variable number of input parameters and return a value of a particular type. A UDF can return either scalar data - a string, an integer, and so forth - or tabular data. Let s take a quick look at both types of UDFs, starting with a UDF that returns a scalar data type.

The following UDF calculates the estimated value of the inventory for a particular product. It does so by taking in three input parameters - the `UnitPrice`, `UnitsInStock`, and `Discontinued` values for a particular product - and returns a value of type `money`. It computes the estimated value of the inventory by multiplying the `UnitPrice` by the `UnitsInStock`. For discontinued items, this value is halved.

```
CREATE FUNCTION udf_ComputeInventoryValue
(
    @UnitPrice money,
    @UnitsInStock smallint,
    @Discontinued bit
)
RETURNS money
AS
BEGIN
    DECLARE @Value decimal
    SET @Value = ISNULL(@UnitPrice, 0) * ISNULL(@UnitsInStock, 0)
    IF @Discontinued = 1
        SET @Value = @Value * 0.5

    RETURN @Value
END
```

Once this UDF has been added to the database, it can be found through Management Studio by expanding the Programmability folder, then Functions, and then Scalar-value Functions. It can be used in a `SELECT` query like so:

```
SELECT ProductID, ProductName, dbo.udf_ComputeInventoryValue
    (UnitPrice, UnitsInStock, Discontinued) as InventoryValue
FROM Products
ORDER BY InventoryValue DESC
```

I have added the `udf_ComputeInventoryValue` UDF to the Northwind database; Figure 23 shows the output of the above `SELECT` query when viewed through Management Studio. Also note that the UDF is listed under the Scalar-value Functions folder in the Object Explorer.

Figure 23: Each Product s Inventory Values is Listed (Click to view full-size image)

UDFs can also return tabular data. For example, we can create a UDF that returns products that belong to a particular category:

```
CREATE FUNCTION dbo.udf_GetProductsByCategoryID
(
    @CategoryID int
)
RETURNS TABLE
AS
RETURN
(
    SELECT ProductID, ProductName, SupplierID, CategoryID,
           QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder,
           ReorderLevel, Discontinued
    FROM Products
    WHERE CategoryID = @CategoryID
)
```

The `udf_GetProductsByCategoryID` UDF accepts a `@CategoryID` input parameter and returns the results of the specified `SELECT` query. Once created, this UDF can be referenced in the `FROM` (or `JOIN`) clause of a `SELECT` query. The following example would return the `ProductID`, `ProductName`, and `CategoryID` values for each of the beverages.

```
SELECT ProductID, ProductName, CategoryID
FROM dbo.udf_GetProductsByCategoryID(1)
```

I have added the `udf_GetProductsByCategoryID` UDF to the Northwind database; Figure 24 shows the output of the above `SELECT` query when viewed through Management Studio. UDFs that return tabular data can be found in the Object Explorer s Table-value Functions folder.

Figure 24: The `ProductID`, `ProductName`, and `CategoryID` are Listed for Each Beverage (Click to view full-size image)

> **NOTE**
>
> For more information on creating and using UDFs, check out Intro to User-Defined Functions. Also check out Advantages and Drawbacks of User-Defined Functions.

Step 10: Creating a Managed UDF

The `udf_ComputeInventoryValue` and `udf_GetProductsByCategoryID` UDFs created in the above examples are T-SQL database objects. SQL Server 2005 also supports managed UDFs, which can be added to the `ManagedDatabaseConstructs` project just like the managed stored procedures from Steps 3 and 5. For this step, let s implement the `udf_ComputeInventoryValue` UDF in managed code.

To add a managed UDF to the `ManagedDatabaseConstructs` project, right-click on the project name in Solution Explorer and choose to Add a New Item. Select the User-Defined Template from the Add New Item dialog box and name the new UDF file `udf_ComputeInventoryValue_Managed.vb`.

Figure 25: Add a New Managed UDF to the `ManagedDatabaseConstructs` Project (Click to view full-size image)

The User-Defined Function template creates a `Partial` class named `UserDefinedFunctions` with a method whose name is the same as the class file s name (`udf_ComputeInventoryValue_Managed` , in this instance). This method is decorated using the `SqlFunction` attribute, which flags the method as a managed UDF.

```
Imports System
Imports System.Data
Imports System.Data.SqlClient
Imports System.Data.SqlTypes
Imports Microsoft.SqlServer.Server
Partial Public Class UserDefinedFunctions
    <Microsoft.SqlServer.Server.SqlFunction()> _
    Public Shared Function udf_ComputeInventoryValue_Managed() As SqlString
        ' Add your code here
        Return New SqlString("Hello")
    End Function
End Class
```

The `udf_ComputeInventoryValue` method currently returns a `SqlString` object and does not accept any input parameters. We need to update the method definition so that it accepts three input parameters - `UnitPrice` , `UnitsInStock` , and `Discontinued` - and returns a `SqlMoney` object. The logic for calculating the inventory value is identical to that in the T-SQL `udf_ComputeInventoryValue` UDF.

```
<Microsoft.SqlServer.Server.SqlFunction()> _
Public Shared Function udf_ComputeInventoryValue_Managed _
    (UnitPrice As SqlMoney, UnitsInStock As SqlInt16, Discontinued As SqlBoolean) _
    As SqlMoney
    Dim inventoryValue As SqlMoney = 0
    If Not UnitPrice.IsNull AndAlso Not UnitsInStock.IsNull Then
        inventoryValue = UnitPrice * UnitsInStock
        If Discontinued = True Then
            inventoryValue = inventoryValue * New SqlMoney(0.5)
        End If
    End If
    Return inventoryValue
End Function
```

Note that the UDF method s input parameters are of their corresponding SQL types: `SqlMoney` for the `UnitPrice` field, `SqlInt16` for `UnitsInStock` , and `SqlBoolean` for `Discontinued` . These data types reflect the types defined in the `Products` table: the `UnitPrice` column is of type `money` , the `UnitsInStock` column of type `smallint` , and the `Discontinued` column of type `bit` .

The code starts by creating a `SqlMoney` instance named `inventoryValue` that is assigned a value of 0. The `Products` table allows for database `NULL` values in the `UnitsInPrice` and `UnitsInStock` columns. Therefore, we need to first check to see if these values contain `NULL` s, which we do through the `SqlMoney` object s `IsNull` property. If both `UnitPrice` and `UnitsInStock` contain non- `NULL` values, then we compute the `inventoryValue` to be the product of the two. Then, if `Discontinued` is true, then we halve the value.

> **NOTE**
>
> The `SqlMoney` object only allows two `SqlMoney` instances to be multiplied together. It does not allow a `SqlMoney` instance to be multiplied by a literal floating-point number. Therefore, to halve `inventoryValue` we multiply it by a new `SqlMoney` instance that has the value 0.5.

Step 11: Deploying the Managed UDF

Now that that the managed UDF has been created, we are ready to deploy it to the Northwind database. As we saw in Step 4, the managed objects in a SQL Server Project are deployed by right-clicking on the project name in the Solution Explorer and choosing the Deploy option from the context menu.

Once you have deployed the project, return to SQL Server Management Studio and refresh the Scalar-valued Functions folder. You should now see two entries:

- `dbo.udf_ComputeInventoryValue` - the T-SQL UDF created in Step 9, and
- `dbo.udf ComputeInventoryValue_Managed` - the managed UDF created in Step 10 that was just deployed.

To test this managed UDF, execute the following query from within Management Studio:

```
SELECT ProductID, ProductName,
       dbo.udf_ComputeInventoryValue_Managed(
                 UnitPrice,
                 UnitsInStock,
                 Discontinued
              ) as InventoryValue
FROM Products
ORDER BY InventoryValue DESC
```

This command uses the managed `udf ComputeInventoryValue_Managed` UDF instead of the T-SQL `udf_ComputeInventoryValue` UDF, but the output is the same. Refer back to Figure 23 to see a screenshot of the UDF s output.

Step 12: Debugging the Managed Database Objects

In the Debugging Stored Procedures tutorial we discussed the three options for debugging SQL Server through Visual Studio: Direct Database Debugging, Application Debugging, and Debugging from a SQL Server Project. Managed database objects cannot be debugged via Direct Database Debugging, but can be debugged from a client application and directly from the SQL Server Project. In order for debugging to work, however, the SQL Server 2005 database must allow SQL/CLR debugging. Recall that when we first created the `ManagedDatabaseConstructs` project Visual Studio asked us whether we wanted to enable SQL/CLR debugging (see Figure 6 in Step 2). This setting can be modified by right-clicking on the database from the Server Explorer window.

Figure 26: Ensure that the Database Allows SQL/CLR Debugging

Imagine that we wanted to debug the `GetProductsWithPriceLessThan` managed stored procedure. We would start by setting a breakpoint within the code of the `GetProductsWithPriceLessThan` method.

Figure 27: Set a Breakpoint in the `GetProductsWithPriceLessThan` Method (Click to view full-size image)

Let s first look at debugging the managed database objects from the SQL Server Project. Since our Solution includes two projects - the `ManagedDatabaseConstructs` SQL Server Project along with our website - in order to debug from the SQL Server Project we need to instruct Visual Studio to launch the `ManagedDatabaseConstructs` SQL Server Project when we start debugging. Right-click the `ManagedDatabaseConstructs` project in Solution Explorer and choose the Set as StartUp Project option from the context menu.

When the `ManagedDatabaseConstructs` project is launched from the debugger it executes the SQL statements in the `Test.sql` file, which is located in the `Test Scripts` folder. For example, to test the `GetProductsWithPriceLessThan` managed stored procedure, replace the existing `Test.sql` file content with the following statement, which invokes the `GetProductsWithPriceLessThan` managed stored procedure passing in the `@CategoryID` value of 14.95:

```
exec GetProductsWithPriceLessThan 14.95
```

Once you ve entered the above script into `Test.sql`, start debugging by going to the Debug menu and choosing

Start Debugging or by hitting F5 or the green play icon in the Toolbar. This will build the projects within the Solution, deploy the managed database objects to the Northwind database, and then execute the `Test.sql` script. At this point, the breakpoint will be hit and we can step through the `GetProductsWithPriceLessThan` method, examine the values of the input parameters, and so on.

Figure 28: The Breakpoint in the `GetProductsWithPriceLessThan` Method Was Hit (Click to view full-size image)

In order for a SQL database object to be debugged through a client application, it is imperative that the database be configured to support application debugging. Right-click on the database in Server Explorer and ensure that the Application Debugging option is checked. Furthermore, we need to configure the ASP.NET application to integrate with the SQL Debugger and to disable connection pooling. These steps were discussed in detail in Step 2 of the Debugging Stored Procedures tutorial.

Once you have configured the ASP.NET application and database, set the ASP.NET website as the startup project and start debugging. If you visit a page that calls one of the managed objects that has a breakpoint, the application will halt and control will be turned over to the debugger, where you can step through the code as shown in Figure 28.

Step 13: Manually Compiling and Deploying Managed Database Objects

SQL Server Projects make it easy to create, compile, and deploy managed database objects. Unfortunately, SQL Server Projects are only available in the Professional and Team Systems editions of Visual Studio. If you are using Visual Web Developer or the Standard Edition of Visual Studio and want to use managed database objects, you will need to manually create and deploy them. This involves four steps:

1. Create a file that contains the source code for the managed database object,
2. Compile the object into an assembly,
3. Register the assembly with the SQL Server 2005 database, and
4. Create a database object in SQL Server that points to the appropriate method in the assembly.

To illustrate these tasks, let s create a new managed stored procedure that returns those products whose `UnitPrice` is greater than a specified value. Create a new file on your computer named `GetProductsWithPriceGreaterThan.vb` and enter the following code into the file (you can use Visual Studio, Notepad, or any text editor to accomplish this):

```
Imports System
Imports System.Data
Imports System.Data.SqlClient
Imports System.Data.SqlTypes
Imports Microsoft.SqlServer.Server
Partial Public Class StoredProcedures
    <Microsoft.SqlServer.Server.SqlProcedure()> _
    Public Shared Sub GetProductsWithPriceGreaterThan(ByVal price As SqlMoney)
        'Create the command
        Dim myCommand As New SqlCommand()
        myCommand.CommandText = _
            "SELECT ProductID, ProductName, SupplierID, CategoryID, " & _
            "       QuantityPerUnit, UnitPrice, UnitsInStock, UnitsOnOrder, " & _
            "       ReorderLevel, Discontinued " & _
            "FROM Products " & _
            "WHERE UnitPrice > @MinPrice"
        myCommand.Parameters.AddWithValue("@MinPrice", price)
        ' Execute the command and send back the results
        SqlContext.Pipe.ExecuteAndSend(myCommand)
    End Sub
End Class
```

This code is nearly identical to that of the `GetProductsWithPriceLessThan` method created in Step 5. The only differences are the method names, the `WHERE` clause, and the parameter name used in the query. Back in the `GetProductsWithPriceLessThan` method, the `WHERE` clause read: `WHERE UnitPrice < @MaxPrice`. Here, in `GetProductsWithPriceGreaterThan`, we use: `WHERE UnitPrice > @MinPrice`.

We now need to compile this class into an assembly. From the command line, navigate to the directory where you saved the `GetProductsWithPriceGreaterThan.vb` file and use the C# compiler (`csc.exe`) to compile the class file into an assembly:

```
vbc.exe /t:library /out:ManuallyCreatedDBObjects.dll GetProductsWithPriceGreaterThan.vb
```

If the folder containing v `bc.exe` in not in the system s `PATH`, you will have to fully reference its path, `%WINDOWS%\Microsoft.NET\Framework\version\`, like so:

```
C:\WINDOWS\Microsoft.NET\Framework\v2.0.50727\vbc.exe /t:library /out:ManuallyCreatedDBObjects.dll
GetProductsWithPriceGreaterThan.vb
```

Figure 29: Compile `GetProductsWithPriceGreaterThan.vb` Into an Assembly (Click to view full-size image)

The `/t` flag specifies that the Visual Basic class file should be compiled into a DLL (rather than an executable). The `/out` flag specifies the name of the resulting assembly.

NOTE

Rather than compiling the `GetProductsWithPriceGreaterThan.vb` class file from the command line you could alternatively use Visual Basic Express Edition or create a separate Class Library project in Visual Studio Standard Edition. S ren Jacob Lauritsen has kindly provided such a Visual Basic Express Edition project with code for the `GetProductsWithPriceGreaterThan` stored procedure and the two managed stored procedures and UDF created in Steps 3, 5, and 10. S ren s project also includes the T-SQL commands needed to add the corresponding database objects.

With the code compiled into an assembly, we are ready to register the assembly within the SQL Server 2005 database. This can be performed through T-SQL, using the command `CREATE ASSEMBLY`, or through SQL Server Management Studio. Let s focus on using Management Studio.

From Management Studio, expand the Programmability folder in the Northwind database. One of its subfolder is Assemblies. To manually add a new Assembly to the database, right-click on the Assemblies folder and choose New Assembly from the context menu. This displays the New Assembly dialog box (see Figure 30). Click on the Browse button, select the `ManuallyCreatedDBObjects.dll` assembly we just compiled, and then click OK to add the Assembly to the database. You should not see the `ManuallyCreatedDBObjects.dll` assembly in the Object Explorer.

Figure 30: Add the `ManuallyCreatedDBObjects.dll` Assembly to the Database (Click to view full-size image)

Figure 31: The `ManuallyCreatedDBObjects.dll` is Listed in the Object Explorer

While we have added the assembly to the Northwind database, we have yet to associate a stored procedure with the `GetProductsWithPriceGreaterThan` method in the assembly. To accomplish this, open a new query window and execute the following script:

```
CREATE PROCEDURE [dbo].[GetProductsWithPriceGreaterThan]
(
    @price money
)
WITH EXECUTE AS CALLER
AS
EXTERNAL NAME [ManuallyCreatedDBObjects].[StoredProcedures].[GetProductsWithPriceGreaterThan]
GO
```

This creates a new stored procedure in the Northwind database named `GetProductsWithPriceGreaterThan` and associates it with the managed method `GetProductsWithPriceGreaterThan` (which is in the class `StoredProcedures`, which is in the assembly `ManuallyCreatedDBObjects`).

After executing the above script, refresh the Stored Procedures folder in the Object Explorer. You should see a new stored procedure entry - `GetProductsWithPriceGreaterThan` - which has a lock icon next to it. To test this stored procedure, enter and execute the following script in the query window:

```
exec GetProductsWithPriceGreaterThan 24.95
```

As Figure 32 shows, the above command displays information for those products with a `UnitPrice` greater than $24.95.

Figure 32: The `ManuallyCreatedDBObjects.dll` is Listed in the Object Explorer (Click to view full-size image)

Summary

Microsoft SQL Server 2005 provides integration with the Common Language Runtime (CLR), which allows database objects to be created using managed code. Previously, these database objects could only be created using T-SQL, but now we can create these objects using .NET programming languages like Visual Basic. In this tutorial we created two managed stored procedures and a managed User-Defined Function.

Visual Studio s SQL Server Project type facilitates creating, compiling, and deploying managed database objects. Moreover, it offers rich debugging support. However, SQL Server Project types are only available in the Professional and Team Systems editions of Visual Studio. For those using Visual Web Developer or the Standard Edition of Visual Studio, the creation, compilation, and deployment steps must be performed manually, as we saw in Step 13.

Happy Programming!

Download PDF

This is the first tutorial in a series of tutorials that will explore techniques for authenticating visitors through a web form, authorizing access to particular pages and functionality, and managing user accounts in an ASP.NET application.

Introduction

What is the one thing forums, eCommerce sites, online email websites, portal websites, and social network sites all have in common? They all offer *user accounts*. Sites that offer user accounts must provide a number of services. At a minimum, new visitors need to be able to create an account and returning visitors must be able to log in. Such web applications can make decisions based on the logged in user: some pages or actions might be restricted to only logged in users, or to a certain subset of users; other pages might show information specific to the logged in user, or might show more or less information, depending on what user is viewing the page.

This is the first tutorial in a series of tutorials that will explore techniques for authenticating visitors through a web form, authorizing access to particular pages and functionality, and managing user accounts in an ASP.NET application. Over the course of these tutorials we will examine how to:

- Identify and log users in to a website
- Use ASP.NET's Membership framework to manage user accounts
- Create, update, and delete user accounts
- Limit access to a web page, directory, or specific functionality based on the logged in user
- Use ASP.NET's Roles framework to associate user accounts with roles
- Manage user roles
- Limit access to a web page, directory, or specific functionality based on the logged in user's role
- Customize and extend ASP.NET's security Web controls

These tutorials are geared to be concise and provide step-by-step instructions with plenty of screen shots to walk you through the process visually. Each tutorial is available in C# and Visual Basic versions and includes a download of the complete code used. (This first tutorial focuses on security concepts from a high-level viewpoint and therefore does not contain any associated code.)

In this tutorial we will discuss important security concepts and what facilities are available in ASP.NET to assist in implementing forms authentication, authorization, user accounts, and roles. Let's get started!

> **NOTE**
>
> Security is an important aspect of any application that spans physical, technological, and policy decisions and requires a high degree of planning and domain knowledge. This tutorial series is not intended as a guide for developing secure web applications. Rather, it focuses specifically on forms authentication, authorization, user accounts, and roles. While some security concepts revolving around these issues are discussed in this series, others are left unexplored.

Authentication, Authorization, User Accounts, and Roles

Authentication, authorization, user accounts, and roles are four terms that will be used very often throughout this tutorial series, so I'd like to take a quick moment to define these terms within the context of web security. In a client-server model, such as the Internet, there are many scenarios in which the server needs to identify the client making the request. *Authentication* is the process of ascertaining the client's identity. A client who has been successfully identified is said to be *authenticated*. An unidentified client is said to be *unauthenticated* or *anonymous*.

Secure authentication systems involve at least one of the following three facets: something you know, something you have, or something you are. Most web applications rely on something the client knows, such as a password or a PIN. The information used to identify a user - her username and password, for example - are referred to as *credentials*. This tutorial series focuses on *forms authentication*, which is an authentication model where users log in to the site by providing their credentials in a web page form. We have all experienced this type of authentication before. Go to any eCommerce site. When you are ready to check out you are asked to log in by entering your username and password into textboxes on a web page.

In addition to identifying clients, a server may need to limit what resources or functionalities are accessible depending on the client making the request. *Authorization* is the process of determining whether a particular user has the authority to access a specific resource or functionality.

A *user account* is a store for persisting information about a particular user. User accounts must minimally include information that uniquely identifies the user, such as the user's login name and password. Along with this essential information, user accounts may include things like: the user's email address; the date and time the account was created; the date and time they last logged in; first and last name; phone number; and mailing address. When using forms authentication, user account information is typically stored in a relational database like Microsoft SQL Server.

Web applications that support user accounts may optionally group users into *roles*. A role is simply a label that is applied to a user and provides an abstraction for defining authorization rules and page-level functionality. For example, a website might include an Administrator role with authorization rules that prohibit anyone but an Administrator to access a particular set of web pages. Moreover, a variety of pages that are accessible to all users (including non-Administrators) might display additional data or offer extra functionality when visited by users in the Administrators role. Using roles, we can define these authorization rules on a role-by-role basis rather than user-by-user.

Authenticating Users in an ASP.NET Application

When a user enters a URL into their browser's address window or clicks on a link, the browser makes a Hypertext Transfer Protocol (HTTP) request to the web server for the specified content, be it an ASP.NET page, an image, a JavaScript file, or any other type of content. The web server is tasked with returning the requested content. In doing so, it must determine a number of things about the request, including who made the request and whether the identity is authorized to retrieve the requested content.

By default, browsers send HTTP requests that lack any sort of identification information. But if the browser does include authentication information then the web server starts the authentication workflow, which attempts to identify the client making the request. The steps of the authentication workflow depend on the type of authentication being used by the web application. ASP.NET supports three types of authentication: Windows, Passport, and forms. This tutorial series focuses on forms authentication, but let's take a minute to compare and contrast Windows authentication user stores and workflow.

Authentication via Windows Authentication

The Windows authentication workflow uses one of the following authentication techniques:

- Basic authentication

- Digest authentication
- Windows Integrated Authentication

All three techniques work in roughly the same way: when an unauthorized, anonymous request arrives, the web server sends back an HTTP response that indicates that authorization is required to continue. The browser then displays a modal dialog box that prompts the user for their username and password (see Figure 1). This information is then sent back to the web server via an HTTP header.

Figure 1: A Modal Dialog Box Prompts the User for His Credentials

The supplied credentials are validated against the web server's Windows User Store. This means that each authenticated user in your web application must have a Windows account in your organization. This is commonplace in intranet scenarios. In fact, when using Windows Integrated Authentication in an intranet setting, the browser automatically provides the web server with the credentials used to log on to the network, thereby suppressing the dialog box shown in Figure 1. While Windows authentication is great for intranet applications, it is usually unfeasible for Internet applications since you do not want to create Windows accounts for each and every user who signs up at your site.

Authentication via Forms Authentication

Forms authentication, on the other hand, is ideal for Internet web applications. Recall that forms authentication identifies the user by prompting them to enter their credentials through a web form. Consequently, when a user attempts to access an unauthorized resource, they are automatically redirected to the login page where they can enter their credentials. The submitted credentials are then validated against a custom user store - usually a database.

After verifying the submitted credentials, a *forms authentication ticket* is created for the user. This ticket indicates that the user has been authenticated and includes identifying information, such as the username. The forms authentication ticket is (typically) stored as a cookie on the client computer. Therefore, subsequent visits to the website include the forms authentication ticket in the HTTP request, thereby enabling the web application to identify the user once they have logged in.

Figure 2 illustrates the forms authentication workflow from a high-level vantage point. Notice how the authentication and authorization pieces in ASP.NET act as two separate entities. The forms authentication system identifies the user (or reports that they are anonymous). The authorization system is what determines whether the user has access to the requested resource. If the user is unauthorized (as they are in Figure 2 when attempting to anonymously visit ProtectedPage.aspx), the authorization system reports that the user is denied, causing the forms authentication system to automatically redirect the user to the login page.

Once the user has successfully logged in, subsequent HTTP requests include the forms authentication ticket. The forms authentication system merely identifies the user - it is the authorization system that determines whether the user can access the requested resource.

Figure 2: The Forms Authentication Workflow

We will dig into forms authentication in much greater detail in the next two tutorials,An Overview of Forms Authentication and Forms Authentication Configuration and Advanced Topics. For more on ASP.NET's authentication options, see ASP.NET Authentication.

Limiting Access to Web Pages, Directories, and Page Functionality

ASP.NET includes two ways to determine whether a particular user has authority to access a specific file or directory:

- **File authorization** - since ASP.NET pages and web services are implemented as files that reside on the web server's file system, access to these files can be specified through Access Control Lists (ACLs). File authorization is most commonly used with Windows authentication because ACLs are permissions that apply to Windows accounts. When using forms authentication, all operating system- and file system-level requests are executed by the same Windows account, regardless of the user visiting the site.
- **URL authorization**- with URL authorization, the page developer specifies authorization rules in Web.config. These authorization rules specify what users or roles are allowed to access or are denied from accessing certain pages or directories in the application.

File authorization and URL authorization define authorization rules for accessing a particular ASP.NET page or for all ASP.NET pages in a particular directory. Using these techniques we can instruct ASP.NET to deny requests to a particular page for a particular user, or allow access to a set of users and deny access to everyone else. What about scenarios where all of the users can access the page, but the page's functionality depends on the user? For example, many sites that support user accounts have pages that display different content or data for authenticated users versus anonymous users. An anonymous user might see a link to log in to the site, whereas an authenticated user would instead see a message like, Welcome back, *Username* along with a link to log out. Another example: when viewing an item at an auction site you see different information depending on whether you are a bidder or the one auctioning the item.

Such page-level adjustments can be accomplished declaratively or programmatically. To show different content for anonymous than authenticated users, simply drag a LoginView control onto your page and enter the appropriate content into its AnonymousTemplate and LoggedInTemplate templates. Alternatively, you can programmatically determine whether the current request is authenticated, who the user is, and what roles they belong to (if any). You can use this information to then show or hide columns in a grid or Panels on the page.

This series includes three tutorials that focus on authorization. ***User-Based Authorization***examines how to limit access to a page or pages in a directory for specific user accounts; ***Role-Based Authorization*** looks at supplying authorization rules at the role level; lastly, the ***Displaying Content Based on the Currently Logged In User*** tutorial explores modifying a particular page's content and functionality based on the user visiting the page. For more on ASP.NET's authorization options, see ASP.NET Authorization.

User Accounts and Roles

ASP.NET's forms authentication provides an infrastructure for users to log in to a site and have their authenticated state remembered across page visits. And URL authorization offers a framework for limiting access to specific files or folders in an ASP.NET application. Neither feature, however, supplies a means for storing user account information or managing roles.

Prior to ASP.NET 2.0, developers were responsible for creating their own user and role stores. They were also on the hook for designing the user interfaces and writing the code for essential user account-related pages like the login page and the page to create a new account, among others. Without any built-in user account framework in ASP.NET, each developer implementing user accounts had to arrive at his own design decisions on questions like, How do I store passwords or other sensitive information? and What guidelines should I impose regarding password length and strength?

Today, implementing user accounts in an ASP.NET application is much simpler thanks to the *Membership framework* and the built-in Login Web controls. The Membership framework is a handful of classes in the System.Web.Security namespace that provide functionality for performing essential user account-related tasks. The key class in the Membership framework is the Membership class, which has methods like:

- CreateUser
- DeleteUser
- GetAllUsers
- GetUser
- UpdateUser
- ValidateUser

The Membership framework uses the provider model, which cleanly separates the Membership framework's API from its implementation. This enables developers to use a common API, but empowers them to use an implementation that meets their application's custom needs. In short, the Membership class defines the essential functionality of the framework (the methods, properties, and events), but does not actually supply any implementation details. Instead, the methods of the Membership class invoke the configured provider, which is what performs the actual work. For example, when the Membership class's CreateUser method is invoked, the Membership class doesn't know the details of the user store. It doesn't know if users are being maintained in a database or in an XML file or in some other store. The Membership class examines the web application's configuration to determine what provider to delegate the call to, and that provider class is responsible for actually creating the new user account in the appropriate user store. This interaction is illustrated in Figure 3.

Microsoft ships two Membership provider classes in the .NET Framework:

- ActiveDirectoryMembershipProvider - implements the Membership API in Active Directory and Active Directory Application Mode (ADAM) servers.
- SqlMembershipProvider - implements the Membership API in a SQL Server database.

This tutorial series focuses exclusively on the SqlMembershipProvider.

Figure 03: The Provider Model Enables Different Implementations to be Seamlessly Plugged Into the Framework (Click to view full-size image)

The benefit of the provider model is that alternative implementations can be developed by Microsoft, third-party vendors, or individual developers and seamlessly plugged into the Membership framework. For example, Microsoft has released a Membership provider for Microsoft Access databases. For more information on the Membership providers, refer to the Provider Toolkit, which includes a walkthrough of the Membership providers, sample custom providers, over 100 pages of documentation on the provider model, and the complete source code for the built-in Membership providers (namely, ActiveDirectoryMembershipProvider and SqlMembershipProvider).

ASP.NET 2.0 also introduced the Roles framework. Like the Membership framework, the Roles framework is built atop the provider model. Its API is exposed via the Roles class and the .NET Framework ships with three provider classes:

- AuthorizationStoreRoleProvider - manages role information in an authorization-manager policy store, such as Active Directory or ADAM.
- SqlRoleProvider - implements roles in a SQL Server database.
- WindowsTokenRoleProvider - associates role information based on the visitor's Windows group. This method is typically used with Windows authentication.

This tutorial series focuses exclusively on the SqlRoleProvider.

Since the provider model includes a single forward-facing API (the Membership and Roles classes), it is possible to build functionality around that API without having to worry about the implementation details - those are handled by the providers selected by the page developer. This unified API allows for Microsoft and third-party vendors to build Web controls that interface with the Membership and Roles frameworks.

ASP.NET ships with a number of Login Web controls for implementing common user account user interfaces. For example, the Login control prompts a user for their credentials, validates them, and then logs them in via forms authentication. The LoginView control offers templates for displaying different markup to anonymous users versus authenticated users, or different markup based on the user's role. And the CreateUserWizard control provides a step-by-step user interface for creating a new user account.

Underneath the covers the various Login controls interact with the Membership and Roles frameworks. Most Login controls can be implemented without having to write a single line of code. We will examine these controls in greater detail in future tutorials, including techniques for extending and customizing their functionality.

Summary

All web applications that support user accounts require similar features, such as: the ability for users to log in and have their log in status remembered across page visits; a web page for new visitors to create an account; and the ability to the page developer to specify what resource, data, and functionality are available to what users or roles. The tasks of authenticating and authorizing users and of managing user accounts and roles is remarkably easy to accomplish in ASP.NET applications thanks to forms authentication, URL authorization, and the Membership and Roles frameworks.

Over the course of the next several tutorials we will examine these aspects by building a working web application from the ground up in a step-by-step fashion. In the next two tutorial we will explore forms authentication in detail. We will see the forms authentication workflow in action, dissect the forms authentication ticket, discuss security concerns, and see how to configure the forms authentication system - all while building a web application that allows visitors to log in and log out.

Happy Programming!

> In this tutorial we will turn from mere discussion to implementation; in particular, we will look at implementing forms authentication. The web application we start constructing in this tutorial will continue to be built upon in subsequent tutorials, as we move from simple forms authentication to membership and roles.
>
> Please see this video for more information on this topic: Using Basic Forms Authentication in ASP.NET.

Introduction

In the preceding tutorial we discussed the various authentication, authorization, and user account options provided by ASP.NET. In this tutorial we will turn from mere discussion to implementation; in particular, we will look at implementing forms authentication. The web application we start constructing in this tutorial will continue to be built upon in subsequent tutorials, as we move from simple forms authentication to membership and roles.

This tutorial begins with an in-depth look at the forms authentication workflow, a topic we touched upon in the previous tutorial. Following that, we will create an ASP.NET website through which to demo the concepts of forms authentication. Next, we will configure the site to use forms authentication, create a simple login page, and see how to determine, in code, whether a user is authenticated and, if so, the username they logged in with.

Understanding the forms authentication workflow, enabling it in a web application, and creating the login and logoff pages are all vital steps in building an ASP.NET application that supports user accounts and authenticates users through a web page. Because of this – and because these tutorials build upon one another - I would encourage you to work through this tutorial in full before moving on to the next one even if you already have had experience configuring forms authentication in past projects.

Understanding the Forms Authentication Workflow

When the ASP.NET runtime processes a request for an ASP.NET resource, such as an ASP.NET page or ASP.NET Web service, the request raises a number of events during its lifecycle. There are events raised at the very beginning and very end of the request, ones raised when the request is being authenticated and authorized, an event raised in the case of an unhandled exception, and so forth. To see a complete listing of the events, refer to the HttpApplication object's events.

HTTP Modules are managed classes whose code is executed in response to a particular event in the request lifecycle. ASP.NET ships with a number of HTTP Modules that perform essential tasks behind the scenes. Two built-in HTTP Modules that are especially relevant to our discussion are:

- `FormsAuthenticationModule` – authenticates the user by inspecting the forms authentication ticket, which is typically included in the user's cookies collection. If no forms authentication ticket is present, the user is anonymous.
- `UrlAuthorizationModule` – determines whether or not the current user is authorized to access the requested URL. This module determines the authority by consulting the authorization rules specified in the application's configuration files. ASP.NET also includes the `FileAuthorizationModule` that determines authority by

consulting the requested file(s) ACLs.

The `FormsAuthenticationModule` attempts to authenticate the user prior to the `UrlAuthorizationModule` (and `FileAuthorizationModule`) executing. If the user making the request is not authorized to access the requested resource, the authorization module terminates the request and returns an HTTP 401 Unauthorized status. In Windows authentication scenarios, the HTTP 401 status is returned to the browser. This status code causes the browser to prompt the user for their credentials via a modal dialog box. With forms authentication, however, the HTTP 401 Unauthorized status is never sent to the browser because the FormsAuthenticationModule detects this status and modifies it to redirect the user to the login page instead (via an HTTP 302 Redirect status).

The login page's responsibility is to determine if the user's credentials are valid and, if so, to create a forms authentication ticket and redirect the user back to the page they were attempting to visit. The authentication ticket is included in subsequent requests to the pages on the website, which the `FormsAuthenticationModule` uses to identify the user.

Figure 1: The Forms Authentication Workflow

Remembering the Authentication Ticket Across Page Visits

After logging in, the forms authentication ticket must be sent back to the web server on each request so that the user remains logged in as they browse the site. This is typically accomplished by placing the authentication ticket in the user's cookies collection. Cookies are small text files that reside on the user's computer and are transmitted in the HTTP headers on each request to the website that created the cookie. Therefore, once the forms authentication ticket has been created and stored in the browser's cookies, each subsequent visit to that site sends the authentication ticket along with the request, thereby identifying the user.

One aspect of cookies is their expiration, which is the date and time at which the browser discards the cookie. When the forms authentication cookie expires, the user can no longer be authenticated and therefore become anonymous. When a user is visiting from a public terminal, chances are they want their authentication ticket to expire when they close their browser. When visiting from home, however, that same user might want the

authentication ticket to be remembered across browser restarts so that they do not have to re-log in each time they visit the site. This decision is often made by the user in the form of a "Remember me" checkbox on the login page. In Step 3 we will examine how to implement a "Remember me" checkbox in the login page. The following tutorial addresses the authentication ticket timeout settings in detail.

> **NOTE**
> It is possible that the user agent used to log on to the website may not support cookies. In such a case, ASP.NET can use cookieless forms authentication tickets. In this mode, the authentication ticket is encoded into the URL. We will look at when cookieless authentication tickets are used and how they are created and managed in the next tutorial.

The Scope of Forms Authentication

The `FormsAuthenticationModule` is managed code that is part of the ASP.NET runtime. Prior to version 7 of Microsoft's Internet Information Services (IIS) web server, there was a distinct barrier between IIS's HTTP pipeline and the ASP.NET runtime's pipeline. In short, in IIS 6 and earlier, the `FormsAuthenticationModule` only executes when a request is delegated from IIS to the ASP.NET runtime. By default, IIS processes static content itself – like HTML pages and CSS and image files – and only hands off requests to the ASP.NET runtime when a page with an extension of .aspx, .asmx, or .ashx is requested.

IIS 7, however, allows for integrated IIS and ASP.NET pipelines. With a few configuration settings you can setup IIS 7 to invoke the FormsAuthenticationModule for *all* requests. Furthermore, with IIS 7 you can define URL authorization rules for files of any type. For more information, see Changes Between IIS6 and IIS7 Security, Your Web Platform Security, and Understanding IIS7 URL Authorization.

Long story short, in versions prior to IIS 7, you can only use forms authentication to protect resources handled by the ASP.NET runtime. Likewise, URL authorization rules are only applied to resources handled by the ASP.NET runtime. But with IIS 7 it is possible to integrate the FormsAuthenticationModule and UrlAuthorizationModule into IIS's HTTP pipeline, thereby extending this functionality to all requests.

Step 1: Creating an ASP.NET Website for this Tutorial Series

In order to reach the widest possible audience, the ASP.NET website we will be building throughout this series will be created with Microsoft's free version of Visual Studio 2008, Visual Web Developer 2008. We will implement the `SqlMembershipProvider` user store in a Microsoft SQL Server 2005 Express Edition database. If you are using Visual Studio 2005 or a different edition of Visual Studio 2008 or SQL Server, don't worry - the steps will be nearly identical and any non-trivial differences will be pointed out.

> **NOTE**
> The demo web application used in each tutorial is available as a download. This downloadable application was created with Visual Web Developer 2008 targeted for the .NET Framework version 3.5. Since the application is targeted for .NET 3.5, its Web.config file includes additional, 3.5-specific configuration elements. Long story short, if you have yet to install .NET 3.5 on your computer then the downloadable web application will not work without first removing the 3.5-specific markup from Web.config.

Before we can configure forms authentication, we first need an ASP.NET website. Start by creating a new file system-based ASP.NET website. To accomplish this, launch Visual Web Developer and then go to the File menu and choose New Web Site, displaying the New Web Site dialog box. Choose the ASP.NET Web Site template, set the Location drop-down list to File System, choose a folder to place the web site, and set the language to C#. This will create a new web site with a Default.aspx ASP.NET page, an App_Data folder, and a Web.config file.

NOTE

Visual Studio supports two modes of project management: Web Site Projects and Web Application Projects. Web Site Projects lack a project file, whereas Web Application Projects mimic the project architecture in Visual Studio .NET 2002/2003 – they include a project file and compile the project's source code into a single assembly, which is placed in the /bin folder. Visual Studio 2005 initially only supported Web Site Projects, although the Web Application Project model was reintroduced with Service Pack 1; Visual Studio 2008 offers both project models. The Visual Web Developer 2005 and 2008 editions, however, only support Web Site Projects. I will be using the Web Site Project model. If you are using a non-Express edition and want to use the Web Application Project model instead, feel free to do so but be aware that there may be some discrepancies between what you see on your screen and the steps you must take versus the screen shots shown and instructions provided in these tutorials.

Figure 2: Create a New File System-Based Web Site (Click to view full-size image)

Adding a Master Page

Next, add a new Master Page to the site in the root directory named Site.master. Master pages enable a page developer to define a site-wide template that can be applied to ASP.NET pages. The main benefit of master pages is that the site's overall appearance can be defined in a single location, thereby making it easy to update or tweak the site's layout.

Figure 3: Add a Master Page Named Site.master to the Website (Click to view full-size image)

Define the site-wide page layout here in the master page. You can use the Design view and add whatever Layout or Web controls you need, or you can manually add the markup by hand in the Source view. I structured my master page's layout to mimic the layout used in my *Working with Data in ASP.NET 2.0* tutorial series (see Figure 4). The master page uses cascading style sheets for positioning and styles with the CSS settings defined in the file Style.css (which is included in this tutorial's associated download). While you cannot tell from the markup shown below, the CSS rules are defined such that the navigation 's content is absolutely positioned so that it appears on the left and has a fixed width of 200 pixels.

```
<%@ Master Language="C#" AutoEventWireup="true" CodeFile="Site.master.cs" Inherits="Site" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Forms Authentication, Authorization, and User Accounts</title>
    <link href="Styles.css" rel="stylesheet" type="text/css" />
</head>
<body>
    <div id="wrapper">
        <form id="form1" runat="server">

            <div id="header">
                <span class="title">User Account Tutorials</span>
            </div>

            <div id="content">
                <asp:contentplaceholder id="MainContent" runat="server">
                  <!-- Page-specific content will go here... -->
                </asp:contentplaceholder>
            </div>

            <div id="navigation">
                TODO: Menu will go here...
            </div>
        </form>
    </div>
</body>
</html>
```

A master page defines both the static page layout and the regions that can be edited by the ASP.NET pages that use the master page. These content editable regions are indicated by the `ContentPlaceHolder` control, which can be seen within the content . Our master page has a single `ContentPlaceHolder` (MainContent), but master page's may have multiple ContentPlaceHolders.

With the markup entered above, switching to the Design view shows the master page's layout. Any ASP.NET pages that use this master page will have this uniform layout, with the ability to specify the markup for the `MainContent` region.

Figure 4: The Master Page, When Viewed Through the Design View (Click to view full-size image)

Creating Content Pages

At this point we have a Default.aspx page in our website, but it does not use the master page we just created. While it is possible to manipulate the declarative markup of a web page to use a master page, if the page doesn't contain any content yet it is easier to just delete the page and re-add it to the project, specifying the master page to use. Therefore, start by deleting Default.aspx from the project.

Next, right-click on the project name in the Solution Explorer and choose to add a new Web Form named Default.aspx. This time, check the "Select master page" checkbox and choose the Site.master master page from the list.

Figure 5: Add a New Default.aspx Page Choosing to Select a Master Page (Click to view full-size image)

Figure 6: Use the Site.master Master Page

> **NOTE**
> If you are using the Web Application Project Model the Add New Item dialog box does not include a "Select master page" checkbox. Instead, you need to add an item of type "Web Content Form." After choosing the "Web Content Form" option and clicking Add, Visual Studio will display the same Select a Master dialog box shown in Figure 6.

The new Default.aspx page's declarative markup includes just a @Page directive specifying the path to the master page file and a Content control for the master page's MainContent ContentPlaceHolder.

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" AutoEventWireup="true" CodeFile="Default.aspx.cs"
Inherits="_Default" Title="Untitled Page" %>
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
</asp:Content>
```

For now, leave Default.aspx empty. We will return to it later in this tutorial to add content.

> **NOTE**
> Our master page includes a section for a menu or some other navigation interface. We will create such an interface in a future tutorial.

Step 2: Enabling Forms Authentication

With the ASP.NET website created, our next task is to enable forms authentication. The application's authentication configuration is specified through the `<authentication>` element in Web.config. The `<authentication>` element contains a single attribute named mode that specifies the authentication model used by the application. This attribute can have one of the following four values:

- **Windows** – as discussed in the preceding tutorial, when an application uses Windows authentication it is the web server's responsibility to authenticate the visitor, and this is usually done through Basic, Digest, or Integrated Windows authentication.
- **Forms**– users are authenticated via a form on a web page.
- **Passport**– users are authenticated using Microsoft's Passport Network.
- **None**– no authentication model is used; all visitors are anonymous.

By default, ASP.NET applications use Windows authentication. To change the authentication type to forms

authentication, then, we need to modify the `<authentication>` element's mode attribute to Forms.

If your project does not yet contain a Web.config file, add one now by right-clicking on the project name in the Solution Explorer, choosing Add New Item, and then adding a Web Configuration file.

Figure 7: If Your Project Does Not Yet Include Web.config, Add It Now (Click to view full-size image)

Next, locate the `<authentication>` element and update it to use forms authentication. After this change, your Web.config file's markup should look similar to the following:

```
<configuration>
    <system.web>
        ... Unrelated configuration settings and comments removed for brevity ...
        <!--
            The <authentication> section enables configuration
            of the security authentication mode used by
            ASP.NET to identify an incoming user.
        -->
        <authentication mode="Forms" />
    </system.web>
</configuration>
```

> **NOTE**
> Since Web.config is an XML file, casing is important. Make sure that you set the mode attribute to Forms, with a capital "F". If you use a different casing, such as "forms", you'll receive a configuration error when visiting the site through a browser.

The `<authentication>` element may optionally include a `<forms>` child element that contains forms authentication-specific settings. For now, let's just use the default forms authentication settings. We will explore the `<forms>` child element in more detail in the next tutorial.

Step 3: Building the Login Page

In order to support forms authentication our website needs a login page. As discussed in the "Understanding the Forms Authentication Workflow" section, the `FormsAuthenticationModule` will automatically redirect the user to the login page if they attempt to access a page that they are not authorized to view. There are also ASP.NET Web controls that will display a link to the login page to anonymous users. This begs the question, "What is the URL of the login page?"

By default, the forms authentication system expects the login page to be named Login.aspx and placed in the root directory of the web application. If you want to use a different login page URL, you can do so by specifying it in Web.config. We will see how to do this in the subsequent tutorial.

The login page has three responsibilities:

1. Provide an interface that allows the visitor to enter their credentials.
2. Determine if the submitted credentials are valid.
3. "Log in" the user by creating the forms authentication ticket.

Creating the Login Page's User Interface

Let's get started with the first task. Add a new ASP.NET page to the site's root directory named Login.aspx and associate it with the Site.master master page.

Figure 8: Add a New ASP.NET Page Named Login.aspx (Click to view full-size image)

The typical login page interface consists of two textboxes – one for the user's name, one for their password – and a button to submit the form. Websites oftentimes include a "Remember me" checkbox that, if checked, persists the resulting authentication ticket across browser restarts.

Add two TextBoxes to Login.aspx and set their `ID` properties to UserName and Password, respectively. Also set Password's `TextMode` property to Password. Next, add a CheckBox control, setting its `ID` property to RememberMe and its `Text` property to "Remember Me". Following that, add a Button named LoginButton whose `Text` property is set to "Login". And finally, add a Label Web control and set its `ID` property to InvalidCredentialsMessage, its `Text` property to "Your username or password is invalid. Please try again.", its `ForeColor` property to Red, and its `Visible` property to False.

At this point your screen should look similar to the screen shot in Figure 9, and your page's declarative syntax should like the following:

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" AutoEventWireup="true" CodeFile="Login.aspx.cs"
Inherits="Login" %>
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
    <h1>
        Login</h1>
    <p>
        Username:
        <asp:TextBox ID="UserName" runat="server"></asp:TextBox></p>
    <p>
        Password:
        <asp:TextBox ID="Password" runat="server" TextMode="Password"></asp:TextBox></p>
    <p>
        <asp:CheckBox ID="RememberMe" runat="server" Text="Remember Me" /> </p>
    <p>
        <asp:Button ID="LoginButton" runat="server" Text="Login" OnClick="LoginButton_Click" /> </p>
    <p>
        <asp:Label ID="InvalidCredentialsMessage" runat="server" ForeColor="Red" Text="Your username or
password is invalid. Please try again."
            Visible="False"></asp:Label> </p>
</asp:Content>
```

Figure 9: The Login Page Contains Two TextBoxes, a CheckBox, a Button, and a Label (Click to view full-size image)

Finally, create an event handler for the LoginButton's Click event. From the Designer, simply double-click the Button control to create this event handler.

Determining If the Supplied Credentials are Valid

We now need to implement task 2 in the Button's Click event handler – determining whether the supplied credentials are valid. In order to do this there needs to be a user store that holds all of the users' credentials so that we can determine if the supplied credentials match up with any known credentials.

Prior to ASP.NET 2.0, developers were responsible for implementing both their own user stores and writing the code to validate the supplied credentials against the store. Most developers would implement the user store in a database, creating a table named Users with columns like UserName, Password, Email, LastLoginDate, and so

forth. This table, then, would have one record per user account. Verifying a user's supplied credentials would involve querying the database for a matching username and then ensuring that the password in the database corresponded to the supplied password.

With ASP.NET 2.0, developers should use one of the Membership providers to manage the user store. In this tutorial series we will be using the SqlMembershipProvider, which uses a SQL Server database for the user store. When using the SqlMembershipProvider we need to implement a specific database schema that includes the tables, views, and stored procedures expected by the provider. We will examine how to implement this schema in the ***Creating the Membership Schema in SQL Server*** tutorial. With the Membership provider in place, validating the user's credentials is as simple as calling the Membership class's ValidateUser(*username*, *password*) method, which returns a Boolean value indicating whether the validity of the *username* and *password* combination. Seeing as we have not yet implemented the SqlMembershipProvider's user store, we cannot use the Membership class's ValidateUser method at this time.

Rather than take the time to build our own custom Users database table (which would be obsolete once we implemented the SqlMembershipProvider), let's instead hard-code the valid credentials within the login page itself. In the LoginButton's Click event handler, add the following code:

```
protected void LoginButton_Click(object sender, EventArgs e)
{
    // Three valid username/password pairs: Scott/password, Jisun/password, and Sam/password.
    string[] users = { "Scott", "Jisun", "Sam" };
    string[] passwords = { "password", "password", "password" };
    for (int i = 0; i < users.Length; i++)
    {
        bool validUsername = (string.Compare(UserName.Text, users[i], true) == 0);
        bool validPassword = (string.Compare(Password.Text, passwords[i], false) == 0);
        if (validUsername && validPassword)
        {
            // TODO: Log in the user...
            // TODO: Redirect them to the appropriate page
        }
    }
    // If we reach here, the user's credentials were invalid
    InvalidCredentialsMessage.Visible = true;
}
```

As you can see, there are three valid user accounts – Scott, Jisun, and Sam – and all three have the same password ("password"). The code loops through the users and passwords arrays looking for a valid username and password match. If both the username and password are valid, we need to login the user and then redirect them to the appropriate page. If the credentials are invalid, then we display the InvalidCredentialsMessage Label.

When a user enters valid credentials, I mentioned that they are then redirected to the "appropriate page." What is the appropriate page, though? Recall that when a user visits a page they are not authorized to view, the FormsAuthenticationModule automatically redirects them to the login page. In doing so, it includes the requested URL in the querystring via the ReturnUrl parameter. That is, if a user attempted to visit ProtectedPage.aspx, and they were not authorized to do so, the FormsAuthenticationModule would redirect them to:

Login.aspx?ReturnUrl=ProtectedPage.aspx

Upon successfully logging in, the user should be redirected back to ProtectedPage.aspx. Alternatively, users may visit the login page on their own volition. In that case, after logging in the user they should be sent to the root folder's Default.aspx page.

Logging In the User

Assuming that the supplied credentials are valid, we need to create a forms authentication ticket, thereby logging in the user to the site. The FormsAuthentication class in the System.Web.Security namespace provides

assorted methods for logging in and logging out users via the forms authentication system. While there are several methods in the FormsAuthentication class, the three we are interested in at this juncture are:

- GetAuthCookie(*username, persistCookie*) – creates a forms authentication ticket for the supplied name *username*. Next, this method creates and returns an HttpCookie object that holds the contents of the authentication ticket. If *persistCookie* is true, a persistent cookie is created.
- SetAuthCookie(*username, persistCookie*) – calls the GetAuthCookie(*username*, *persistCookie*) method to generate the forms authentication cookie. This method then adds the cookie returned by GetAuthCookie to the Cookies collection (assuming cookies-based forms authentication is being used; otherwise, this method calls an internal class that handles the cookieless ticket logic).
- RedirectFromLoginPage(*username, persistCookie*) – this method calls SetAuthCookie(*username*, *persistCookie*), and then redirects the user to the appropriate page.

GetAuthCookie is handy when you need to modify the authentication ticket before writing the cookie out to the Cookies collection. SetAuthCookie is useful if you want to create the forms authentication ticket and add it to the Cookies collection, but do not want to redirect the user to the appropriate page. Perhaps you want to keep them on the login page or send them to some alternate page.

Since we want to log in the user and redirect them to the appropriate page, let's use RedirectFromLoginPage. Update the LoginButton's Click event handler, replacing the two commented TODO lines with the following line of code:

FormsAuthentication.RedirectFromLoginPage(UserName.Text, RememberMe.Checked);

When creating the forms authentication ticket we use the UserName TextBox's Text property for the forms authentication ticket *username* parameter, and the checked state of the RememberMe CheckBox for the *persistCookie* parameter.

To test the login page, visit it in a browser. Start by entering invalid credentials, such as a username of "Nope" and a password of "wrong". Upon clicking the Login button a postback will occur and the InvalidCredentialsMessage Label will be displayed.

Figure 10: The InvalidCredentialsMessage Label is Displayed When Entering Invalid Credentials (Click to view full-size image)

Next, enter valid credentials and click the Login button. This time when the postback occurs a forms authentication ticket is created and you are automatically redirected back to Default.aspx. At this point you have logged in to the website, although there are no visual cues to indicate that you are currently logged in. In Step 4 we will see how to programmatically determine whether a user is logged in or not as well as how to identify the

user visiting the page.

Step 5 examines techniques for logging a user out of the website.

Securing the Login Page

When the user enters her credentials and submits the login page form, the credentials – including her password – are transmitted over the Internet to the web server in *plain text*. That means any hacker sniffing the network traffic can see the username and password. To prevent this, it is essential to encrypt the network traffic by using Secure Socket Layers (SSL). This will ensure that the credentials (as well as the entire page's HTML markup) are encrypted from the moment they leave the browser until they are received by the web server.

Unless your website contains sensitive information, you will only need to use SSL on the login page and on other pages where the user's password would otherwise be sent over the wire in plain text. You do not need to worry about securing the forms authentication ticket since, by default, it is both encrypted and digitally signed (to prevent tampering). A more thorough discussion on forms authentication ticket security is presented in the following tutorial.

> **NOTE**
>
> Many financial and medical websites are configured to use SSL on *all* pages accessible to authenticated users. If you are building such a website you can configure the forms authentication system so that the forms authentication ticket is only transmitted over a secure connection. We will look at the various forms authentication configuration options in the next tutorial, *Forms Authentication Configuration and Advanced Topics*.

Step 4: Detecting Authenticated Visitors and Determining Their Identity

At this point we have enabled forms authentication and created a rudimentary login page, but we have yet to examine how we can determine whether a user is authenticated or anonymous. In certain scenarios we may wish to display different data or information depending on whether an authenticated or anonymous user is visiting the page. Moreover, we oftentimes need to know the identity of the authenticated user.

Let's augment the existing Default.aspx page to illustrate these techniques. In Default.aspx add two Panel controls, one named AuthenticatedMessagePanel and another named AnonymousMessagePanel. Add a Label control named WelcomeBackMessage in the first Panel. In the second Panel add a HyperLink control, set its Text property to "Log In" and its NavigateUrl property to "~/Login.aspx". At this point the declarative markup for Default.aspx should look similar to the following:

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" AutoEventWireup="true" CodeFile="Default.aspx.cs"
Inherits="_Default" Title="Untitled Page" %>
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
    <asp:Panel runat="server" ID="AuthenticatedMessagePanel">
        <asp:Label runat="server" ID="WelcomeBackMessage"></asp:Label>
    </asp:Panel>

    <asp:Panel runat="Server" ID="AnonymousMessagePanel">
        <asp:HyperLink runat="server" ID="lnkLogin" Text="Log In" NavigateUrl="~/Login.aspx">
</asp:HyperLink>
    </asp:Panel>
</asp:Content>
```

As you have probably guessed by now, the idea here is to display just the AuthenticatedMessagePanel to authenticated visitors and just the AnonymousMessagePanel to anonymous visitors. To accomplish this we need to set these Panels' Visible properties depending on whether the user is logged in or not.

The Request.IsAuthenticated property returns a Boolean value indicating whether the request has been

authenticated. Enter the following code into the Page_Load event handler code:

```
protected void Page_Load(object sender, EventArgs e)
{
    if (Request.IsAuthenticated)
    {
        WelcomeBackMessage.Text = "Welcome back!";

        AuthenticatedMessagePanel.Visible = true;
        AnonymousMessagePanel.Visible = false;
    }
    else
    {
        AuthenticatedMessagePanel.Visible = false;
        AnonymousMessagePanel.Visible = true;
    }
}
```

With this code in place, visit Default.aspx through a browser. Assuming that you have yet to log in, you will see a link to the login page (see Figure 11). Click this link and log in to the site. As we saw in Step 3, after entering your credentials you will be returned to Default.aspx, but this time the page shows the "Welcome back!" message (see Figure 12).

Figure 11: When Visiting Anonymously, a Log In Link is Displayed

Figure 12: Authenticated Users are Shown the "Welcome back!" Message

We can determine the currently logged on user's identity via the HttpContext object's User property. The HttpContext object represents information about the current request, and is the home for such common ASP.NET objects as Response, Request, and Session, among others. The User property represents the security context of the current HTTP request and implements the IPrincipal interface.

The User property is set by the FormsAuthenticationModule. Specifically, when the FormsAuthenticationModule finds a forms authentication ticket in the incoming request, it creates a new GenericPrincipal object and assigns it to the User property.

Principal objects (like GenericPrincipal) provide information on the user's identity and the roles to which they belong. The IPrincipal interface defines two members:

- IsInRole(*roleName*) – a method that returns a Boolean value indicating if the principal belongs to the specified role.
- Identity – a property that returns an object that implements the IIdentity interface. The IIdentity interface defines three properties: AuthenticationType, IsAuthenticated, and Name.

We can determine the name of the current visitor using the following code:

string currentUsersName = User.Identity.Name;

When using forms authentication, a FormsIdentity object is created for the GenericPrincipal's Identity property. The FormsIdentity class always returns the string "Forms" for its AuthenticationType property and true for its IsAuthenticated property. The Name property returns the username specified when creating the forms authentication ticket. In addition to these three properties, FormsIdentity includes access to the underlying authentication ticket via its Ticket property. The Ticket property returns an object of type FormsAuthenticationTicket, which has properties like Expiration, IsPersistent, IssueDate, Name, and so on.

The important point to take away here is that the *username* parameter specified in the FormsAuthentication.GetAuthCookie(*username*, *persistCookie*), FormsAuthentication.SetAuthCookie(*username*, *persistCookie*), and FormsAuthentication.RedirectFromLoginPage(*username*, *persistCookie*) methods is the same value returned by User.Identity.Name. Moreover, the authentication ticket created by these methods is available by casting User.Identity to a FormsIdentity object and then accessing the Ticket property:

```
FormsIdentity ident = User.Identity as FormsIdentity;
FormsAuthenticationTicket authTicket = ident.Ticket;
```

Let's provide a more personalized message in Default.aspx. Update the Page_Load event handler so that the WelcomeBackMessage Label's Text property is assigned the string "Welcome back, *username*!"

WelcomeBackMessage.Text = "Welcome back, " + User.Identity.Name + "!";

Figure 13 shows the effect of this modification (when logging in as user Scott).

Figure 13: The Welcome Message Includes the Currently Logged In User's Name

Using the LoginView and LoginName Controls

Displaying different content to authenticated and anonymous users is a common requirement; so is displaying the name of the currently logged on user. For that reason, ASP.NET includes two Web controls that provide the same functionality shown in Figure 13, but without the need to write a single line of code.

The LoginView control is a template-based Web control that makes it easy to display different data to authenticated and anonymous users. The LoginView includes two predefined templates:

- AnonymousTemplate – any markup added to this template is only displayed to anonymous visitors.
- LoggedInTemplate – this template's markup is shown only to authenticated users.

Let's add the LoginView control to our site's master page, Site.master. Rather than adding just the LoginView control, though, let's add both a new ContentPlaceHolder control and then put the LoginView control within that new ContentPlaceHolder. The rationale for this decision will become apparent shortly.

> **NOTE**
> In addition to the AnonymousTemplate and LoggedInTemplate, the LoginView control can include role-specific templates. Role-specific templates show markup only to those users that belong to a specified role. We will examine the role-based features of the LoginView control in a future tutorial.

Start by adding a ContentPlaceHolder named LoginContent into the master page within the navigation element. You can simply drag a ContentPlaceHolder control from the Toolbox onto the Source view, placing the resulting markup right above the "TODO: Menu will go here..." text.

```
<div id="navigation">
    <asp:ContentPlaceHolder ID="LoginContent" runat="server">
    </asp:ContentPlaceHolder>

    TODO: Menu will go here...
</div>
```

Next, add a LoginView control within the LoginContent ContentPlaceHolder. Content placed into the master page's ContentPlaceHolder controls are considered *default content* for the ContentPlaceHolder. That is, ASP.NET pages that use this master page can specify their own content for each ContentPlaceHolder or use the master page's default content.

The LoginView and other login-related controls are located in the Toolbox's Login tab.

Figure 14: The LoginView Control in the Toolbox

Next, add two <br /> elements immediately after the LoginView control, but still within the ContentPlaceHolder. At this point, the navigation element's markup should look like the following:

```
<div id="navigation">
    <asp:ContentPlaceHolder ID="LoginContent" runat="server">
        <asp:LoginView ID="LoginView1" runat="server">
        </asp:LoginView>
        <br /><br />
    </asp:ContentPlaceHolder>

    TODO: Menu will go here...
</div>
```

The LoginView's templates can be defined from the Designer or the declarative markup. From Visual Studio's Designer, expand the LoginView's smart tag, which lists the configured templates in a drop-down list. Type in the text "Hello, stranger" into the AnonymousTemplate; next, add a HyperLink control and set its Text and NavigateUrl properties to "Log In" and "~/Login.aspx", respectively.

After configuring the AnonymousTemplate, switch to the LoggedInTemplate and enter the text, "Welcome back, ". Then drag a LoginName control from the Toolbox into the LoggedInTemplate, placing it immediately after the "Welcome back, " text. The LoginName control, as its name implies, displays the name of the currently logged in user. Internally, the LoginName control simply outputs the User.Identity.Name property

After making these additions to the LoginView's templates, the markup should look similar to the following:

```
<div id="navigation">
    <asp:ContentPlaceHolder ID="LoginContent" runat="server">
        <asp:LoginView ID="LoginView1" runat="server">
            <LoggedInTemplate>
                Welcome back,
                <asp:LoginName ID="LoginName1" runat="server" />.
            </LoggedInTemplate>
            <AnonymousTemplate>
                Hello, stranger.
                <asp:HyperLink ID="lnkLogin" runat="server" NavigateUrl="~/Login.aspx">Log
In</asp:HyperLink>
            </AnonymousTemplate>
        </asp:LoginView>

        <br /><br />
    </asp:ContentPlaceHolder>

    TODO: Menu will go here...
</div>
```

With this addition to the Site.master master page, each page in our website will display a different message depending on whether the user is authenticated. Figure 15 shows the Default.aspx page when visited through a browser by user Jisun. The "Welcome back, Jisun" message is repeated twice: once in the master page's navigation section on the left (via the LoginView control we just added) and once in the Default.aspx's content area (via Panel controls and programmatic logic).

Figure 15: The LoginView Control Displays "Welcome back, Jisun."

Because we added the LoginView to the master page, it can appear in every page on our site. However, there may be web pages where we don't want to show this message. One such page is the login page, since a link to the login page seems out of place there. Since we placed the LoginView control in a ContentPlaceHolder in the master page, we can override this default markup in our content page. Open Login.aspx and go to the Designer. Since we have not explicitly defined a Content control in Login.aspx for the LoginContent ContentPlaceHolder in the master page, the login page will show the master page's default markup for this ContentPlaceHolder. You can see this through the Designer – the LoginContent ContentPlaceHolder shows the default markup (the LoginView control).

Figure 16: The Login Page Shows the Default Content for the Master Page's LoginContent ContentPlaceHolder (Click to view full-size image)

To override the default markup for the LoginContent ContentPlaceHolder, simply right-click on the region in the Designer and choose the Create Custom Content option from the context menu. (When using Visual Studio 2008 the ContentPlaceHolder includes a smart tag that, when selected, offers the same option.) This adds a new Content control to the page's markup and thereby allows us to define custom content for this page. You could add a custom message here, such as "Please log in...", but let's just leave this blank.

> **NOTE**
>
> In Visual Studio 2005, creating custom content creates an empty Content control in the ASP.NET page. In Visual Studio 2008, however, creating custom content copies the master page's default content into the newly created Content control. If you are using Visual Studio 2008, then, after creating the new Content control make sure to clear out the content copied over from the master page.

Figure 17 shows the Login.aspx page when visited from a browser after making this change. Note that there is no "Hello, stranger" or "Welcome back, *username*" message in the left navigation as there is when visiting Default.aspx.

Figure 17: The Login Page Hides the Default LoginContent ContentPlaceHolder's Markup (Click to view full-size image)

Step 5: Logging Out

In Step 3 we looked at building a login page to log a user in to the site, but we have yet to see how to log a user out. In addition to methods for logging a user in, the FormsAuthentication class also provides a SignOut method. The SignOut method simply destroys the forms authentication ticket, thereby logging the user out of the site.

Offering a log out link is such a common feature that ASP.NET includes a control specifically designed to log a user out. The LoginStatus control displays either a "Login" LinkButton or a "Logout" LinkButton, depending on the user's authentication status. A "Login" LinkButton is rendered for anonymous users, whereas a "Logout" LinkButton is displayed to authenticated users. The text for the "Login" and "Logout" LinkButtons can be configured via the LoginStatus's LoginText and LogoutText properties.

Clicking the "Login" LinkButton causes a postback, from which a redirect is issued to the login page. Clicking the "Logout" LinkButton causes the LoginStatus control to invoke the FormsAuthentication.SignOff method and then redirects the user to a page. The page the logged off user is redirected to depends on the LogoutAction property, which can be assigned to one of the three following values:

- Refresh – the default; redirects the user to the page they were just visiting. If the page they were just visiting does not allow anonymous users, then the FormsAuthenticationModule will automatically redirect the user to the login page.

You may be curious as to why a redirect is performed here. If the user wants to remain on the same page, why the need for the explicit redirect? The reason is because when the "Logoff" LinkButton is clicked, the user still has the forms authentication ticket in their cookies collection. Consequently, the postback request is an authenticated request. The LoginStatus control calls the SignOut method, but that happens after the FormsAuthenticationModule has authenticated the user. Therefore, an explicit redirect causes the browser to re-request the page. By the time the browser re-requests the page, the forms authentication ticket has been removed and therefore the incoming request is anonymous.

- Redirect – the user is redirected to the URL specified by the LoginStatus's LogoutPageUrl property.
- RedirectToLoginPage – the user is redirected to the login page.

Let's add a LoginStatus control to the master page and configure it to use the Redirect option to send the user to a page that displays a message confirming that they have been signed out. Start by creating a page in the root

directory named Logout.aspx. Don't forget to associate this page with the Site.master master page. Next, enter a message in the page's markup explaining to the user that they have been logged out.

Next, return to the Site.master master page and add a LoginStatus control beneath the LoginView in the LoginContent ContentPlaceHolder. Set the LoginStatus control's LogoutAction property to Redirect and its LogoutPageUrl property to "~/Logout.aspx".

```
<div id="navigation">
    <asp:ContentPlaceHolder ID="LoginContent" runat="server">
        <asp:LoginView ID="LoginView1" runat="server">
            <LoggedInTemplate>
                Welcome back,
                <asp:LoginName ID="LoginName1" runat="server" />.
            </LoggedInTemplate>
            <AnonymousTemplate>
                Hello, stranger.
                <asp:HyperLink ID="lnkLogin" runat="server" NavigateUrl="~/Login.aspx">Log
In</asp:HyperLink>
            </AnonymousTemplate>
        </asp:LoginView>
        <br />
        <asp:LoginStatus ID="LoginStatus1" runat="server" LogoutAction="Redirect"
LogoutPageUrl="~/Logout.aspx" />

        <br /><br />
    </asp:ContentPlaceHolder>

    TODO: Menu will go here...
</div>
```

Since the LoginStatus is outside of the LoginView control, it will appear for both anonymous and authenticated users, but that's OK because the LoginStatus will correctly display a "Login" or "Logout" LinkButton. With the addition of the LoginStatus control, the "Log In" HyperLink in the AnonymousTemplate is superfluous, so remove it.

Figure 18 shows Default.aspx when Jisun visits. Note that the left column displays the message, "Welcome back, Jisun" along with a link to log out. Clicking the log out LinkButton causes a postback, signs Jisun out of the system, and then redirects her to Logout.aspx. As Figure 19 shows, by the time Jisun reaches Logout.aspx she has already been signed out and is therefore anonymous. Consequently, the left column shows the text "Welcome, stranger" and a link to the login page.

Figure 18: Default.aspx Shows "Welcome Back, Jisun" Along with a "Logout" LinkButton (Click to view full-size image)

Figure 19: Logout.aspx Shows "Welcome, stranger" Along with a "Login" LinkButton (Click to view full-size image)

> **NOTE**
>
> I encourage you to customize the Logout.aspx page to hide the master page's LoginContent ContentPlaceHolder (like we did for Login.aspx in Step 4). The reason is because the "Login" LinkButton rendered by the LoginStatus control (the one beneath "Hello, stranger") sends the user to the login page passing the current URL in the ReturnUrl querystring parameter. In short, if a user who has logged out clicks this LoginStatus's "Login" LinkButton, and then logs in, they will be redirected back to Logout.aspx, which could easily confuse the user.

Summary

In this tutorial we started with an examination of the forms authentication workflow and then turned to implementing forms authentication in an ASP.NET application. Forms authentication is powered by the FormsAuthenticationModule, which has two responsibilities: identifying users based on their forms authentication ticket, and redirecting unauthorized users to the login page.

The .NET Framework's FormsAuthentication class includes methods for creating, inspecting, and removing forms authentication tickets. The Request.IsAuthenticated property and User object provide additional programmatic support for determining whether a request is authenticated and information about the user's identity. There are also the LoginView, LoginStatus, and LoginName Web controls, which give developers a quick, code-free way for performing many common login-related tasks. We will examine these and other login-related Web controls in greater detail in future tutorials.

This tutorial provided a cursory overview of forms authentication. We did not examine the assorted configuration options, look at how cookieless forms authentication tickets work, or explore how ASP.NET protects the contents of the forms authentication ticket. We will discuss these topics and more in the next tutorial.

Happy Programming!

Forms Authentication Configuration and Advanced Topics (C#)

2/20/2020 • 38 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will examine the various forms authentication settings and see how to modify them through the forms element. This will entail a detailed look at customizing the forms authentication ticket's timeout value, using a login page with a custom URL (like SignIn.aspx instead of Login.aspx), and cookieless forms authentication tickets.

Introduction

In the previous tutorial we looked at the steps necessary for implementing forms authentication in an ASP.NET application, from specifying configuration settings in Web.config to creating a log in page to displaying different content for authenticated and anonymous users. Recall that we configured the website to use forms authentication by setting the mode attribute of the <authentication> element to Forms. The <authentication> element may optionally include a <forms> child element, through which an assortment of forms authentication settings may be specified.

In this tutorial we will examine the various forms authentication settings and see how to modify them through the <forms> element. This will entail a detailed look at customizing the forms authentication ticket's timeout value, using a login page with a custom URL (like SignIn.aspx instead of Login.aspx), and cookieless forms authentication tickets. We will also examine the makeup of the forms authentication ticket more closely and see the precautions ASP.NET takes to ensure that the ticket's data is secure from inspection and tampering. Finally, we will look at how to store extra user data in the forms authentication ticket and how to model this data through a custom principal object.

Step 1: Examining the <forms> Configuration Settings

The forms authentication system in ASP.NET offers a number of configuration settings that can be customized on an application-by-application basis. This includes settings like: the lifetime of the forms authentication ticket; what sort of protection is applied to the ticket; under what conditions cookieless authentication tickets are used; the path to the login page; and other information. To modify the default values, add a <forms> element as a child of the <authentication> element, specifying those property values you want to customize as XML attributes like so:

```
<authentication mode="Forms">

  <forms

 propertyName1="value1"

 propertyName2="value2"

  ...

 propertyNameN="valueN"

  />

</authentication>
```

Table 1 summarizes the properties that can be customized through the <forms> element. Since Web.config is an XML file, the attribute names in the left column are case-sensitive.

ATTRIBUTE	DESCRIPTION
cookieless	This attribute specifies under what conditions the authentication ticket is stored in a cookie versus being embedded in the URL. Allowable values are: UseCookies; UseUri; AutoDetect; and UseDeviceProfile (the default). Step 2 examines this setting in more detail.
defaultUrl	Indicates the URL that users are redirected to after signing in from the login page if there is no RedirectUrl value specified in the querystring. The default value is default.aspx.
domain	When using cookie-based authentication tickets, this setting specifies the cookie's domain value. The default value is an empty string, which causes the browser to use the domain from which it was issued (such as www.yourdomain.com). In this case, the cookie will **not** be sent when making requests to subdomains, such as admin.yourdomain.com. If you want the cookie to be passed to all subdomains you need to customize the domain attribute setting it to yourdomain.com.
enableCrossAppRedirects	A Boolean value indicating whether authenticated users are remembered when redirected to URLs in other web applications on the same server. The default is false.
loginUrl	The URL of the login page. The default value is login.aspx.
name	When using cookie-based authentication tickets, the name of the cookie. The default is .ASPXAUTH.
path	When using cookie-based authentication tickets, this setting specifies the cookie's path attribute. The path attribute enables a developer to limit the scope of a cookie to a particular directory hierarchy. The default value is /, which informs the browser to send the authentication ticket cookie to any request made to the domain.

ATTRIBUTE	DESCRIPTION
protection	Indicates what techniques are used to protect the forms authentication ticket. The allowable values are: All (the default); Encryption; None; and Validation. These settings are discussed in detail in Step 3.
requireSSL	A Boolean value that indicates whether an SSL connection is required to transmit the authentication cookie. The default value is false.
slidingExpiration	A Boolean value that indicates whether the authentication cookie's timeout is reset each time the user visits the site during a single session. The default value is true. The authentication ticket timeout policy is discussed in more detail in the Specifying the Ticket's Timeout Value section.
timeout	Specifies the time, in minutes, after which the authentication ticket cookie expires. The default value is 30. The authentication ticket timeout policy is discussed in more detail in the Specifying the Ticket's Timeout Value section.

Table 1: A Summary of the <forms> Element's Attributes

In ASP.NET 2.0 and beyond, the default forms authentication values are hard-coded in the FormsAuthenticationConfiguration class in the .NET Framework. Any modifications must be applied on an application-by-application basis in the Web.config file. This differs from ASP.NET 1.x, where the default forms authentication values were stored in the machine.config file (and could therefore be modified via editing machine.config). While on the topic of ASP.NET 1.x, it is worthwhile to mention that a number of the forms authentication system settings have different default values in ASP.NET 2.0 and beyond than in ASP.NET 1.x. If you are migrating your application from an ASP.NET 1.x environment, it is important to be aware of these differences. Consult the <forms> element technical documentation for a list of the differences.

> **NOTE**
> Several forms authentication settings, such as the timeout, domain, and path, specify details for the resulting forms authentication ticket cookie. For more information on cookies, how they work, and their various properties, read this Cookies tutorial.

Specifying the Ticket's Timeout Value

The forms authentication ticket is a token that represents an identity. With cookie-based authentication tickets, this token is held in the form of a cookie and sent to the web server on each request. Possession of the token, in essence, declares, I am *username*, I have already logged in, and is used so that a user's identity can be remembered across page visits.

The forms authentication ticket not only includes the user's identity, but also contains information to help ensure the integrity and security of the token. After all, we don't want a nefarious user to be able to create a counterfeit token, or to modify a legit token in some underhanded way.

One such bit of information included in the ticket is an *expiry*, which is the date and time the ticket is no longer valid. Each time the FormsAuthenticationModule inspects an authentication ticket, it ensures that the ticket's expiry has not yet passed. If it has, it disregards the ticket and identifies the user as being anonymous. This safeguard helps protect against replay attacks. Without an expiry, if a hacker was able to get her hands on a user's valid authentication ticket - perhaps by gaining physical access to their computer and rooting through their cookies - they could send a request to the server with this stolen authentication ticket and gain entry. While

the expiry doesn't prevent this scenario, it does limit the window during which such an attack can succeed.

> **NOTE**
>
> Step 3 details additional techniques used by the forms authentication system to protect the authentication ticket.

When creating the authentication ticket, the forms authentication system determines its expiry by consulting the timeout setting. As noted in Table 1, the timeout setting defaults to 30 minutes, meaning that when the forms authentication ticket is created its expiry is set to a date and time 30 minutes in the future.

The expiry defines an absolute time in the future when the forms authentication ticket expires. But usually developers want to implement a sliding expiry, one that is reset every time the user revisits the site. This behavior is determined by the slidingExpiration settings. If set to true (the default), each time the FormsAuthenticationModule authenticates a user, it updates the ticket's expiry. If set to false, the expiry is not updated on each request, thereby causing the ticket to expire exactly timeout number of minutes past when the ticket was first created.

> **NOTE**
>
> The expiry stored in the authentication ticket is an absolute date and time value, like August 2, 2008 11:34 AM. Moreover, the date and time are relative to the web server's local time. This design decision can have some interesting side effects around Daylight Saving Time (DST), which is when clocks in the United States are moved ahead one hour (assuming the web server is hosted in a locale where Daylight Saving Time is observed). Consider what would happen for an ASP.NET website with a 30 minute expiry near the time that DST begins (which is at 2:00 AM). Imagine a visitor signs on to the site on March 11, 2008 at 1:55 AM. This would generate a forms authentication ticket that expires at March 11, 2008 at 2:25 AM (30 minutes in the future). However, once 2:00 AM rolls around, the clock jumps to 3:00 AM because of DST. When the user loads a new page six minutes after signing in (at 3:01 AM), the FormsAuthenticationModule notes that the ticket has expired and redirects the user to the login page. For a more thorough discussion on this and other authentication ticket timeout oddities, as well as workarounds, pick up a copy of Stefan Schackow's *Professional ASP.NET 2.0 Security, Membership, and Role Management* (ISBN: 978-0-7645-9698-8).

Figure 1 illustrates the workflow when slidingExpiration is set to false and timeout is set to 30. Note that the authentication ticket generated at login contains the expiration date, and this value is not updated on subsequent requests. If the FormsAuthenticationModule finds that the ticket has expired, it discards it and treats the request as anonymous.

Figure 01: A Graphical Representation of the Forms Authentication Ticket's Expiry When slidingExpiration is false(Click to view full-size image)

Figure 2 shows the workflow when slidingExpiration is set to true and timeout is set to 30. When an authenticated request is received (with a non-expired ticket) its expiry is updated to timeout number of minutes in the future.

Figure 02: A Graphical Representation of the Forms Authentication Ticket's When slidingExpiration is true (Click to view full-size image)

When using cookie-based authentication tickets (the default), this discussion becomes a little more confusing because cookies can also have their own expiries specified. A cookie's expiry (or lack thereof) instructs the browser when the cookie should be destroyed. If the cookie lacks an expiry, it is destroyed when the browser shuts down. If an expiry is present, however, the cookie remains stored on the user's computer until the date and time specified in the expiry has passed. When a cookie is destroyed by the browser, it is no longer sent to the web server. Therefore, the destruction of a cookie is analogous to the user logging out of the site.

> **NOTE**
>
> Of course, a user may proactively remove any cookies stored on their computer. In Internet Explorer 7, you would go to Tools, Options, and click the Delete button in the Browsing history section. From there, click the Delete cookies button.

The forms authentication system creates session-based or expiry-based cookies depending on the value passed in to the *persistCookie* parameter. Recall that the FormsAuthentication class's GetAuthCookie, SetAuthCookie, and RedirectFromLoginPage methods take in two input parameters: *username* and *persistCookie*. The login page we created in the preceding tutorial included a Remember me CheckBox, which determined whether a persistent cookie was created. Persistent cookies are expiry-based; non-persistent cookies are session-based.

The timeout and slidingExpiration concepts already discussed apply the same to both session- and expiry-based cookies. There is only one minor difference in execution: when using expiry-based cookies with slidingTimeout set to true, the cookie's expiry is only updated when more than half of the specified time has elapsed.

Let's update our website's authentication ticket timeout policies so that tickets timeout after one hour (60 minutes), using a sliding expiration. To effect this change, update the Web.config file, adding a <forms> element to the <authentication> element with the following markup:

```
<authentication mode="Forms">

  <forms

  slidingExpiration="true"

  timeout="60"

  />

</authentication>
```

Using an Login Page URL Other than Login.aspx

Since the FormsAuthenticationModule automatically redirects unauthorized users to the login page, it needs to know the login page's URL. This URL is specified by the loginUrl attribute in the <forms> element and defaults to login.aspx. If you are porting over an existing website, you may already have a login page with a different URL, one that has already been bookmarked and indexed by search engines. Rather than renaming your existing login page to login.aspx and breaking links and users' bookmarks, you can instead modify the loginUrl attribute to point to your login page.

For example, if your login page was named SignIn.aspx and was located in the Users directory, you could point the loginUrl configuration setting to ~/Users/SignIn.aspx like so:

```
<authentication mode="Forms">

  <forms

  loginUrl="~/Users/SignIn.aspx"

  />

</authentication>
```

Since our current application already has a login page named Login.aspx, there's no need to specify a custom value in the <forms> element.

Step 2: Using Cookieless Forms Authentication Tickets

By default the forms authentication system determines whether to store its authentication tickets in the cookies collection or embed them in the URL based on the user agent visiting the site. All mainstream desktop browsers like Internet Explorer, Firefox, Opera, and Safari, support cookies, but not all mobile devices do.

The cookie policy used by the forms authentication system depends on the cookieless setting in the <forms> element, which can be assigned one of four values:

- UseCookies - specifies that cookie-based authentication tickets will always be used.
- UseUri - indicates that cookie-based authentication tickets will never be used.
- AutoDetect - if the device profile does not support cookies, cookie-based authentication tickets are not used; if the device profile supports cookies, a probing mechanism is used to determine if cookies are enabled.
- UseDeviceProfile - the default; uses cookie-based authentication tickets only if the device profile supports cookies. No probing mechanism is used.

The AutoDetect and UseDeviceProfile settings rely on a *device profile* in ascertaining whether to use cookie-based or cookieless authentication tickets. ASP.NET maintains a database of various devices and their capabilities, such as whether they support cookies, what version of JavaScript they support, and so on. Each time a device requests a web page from a web server it sends along a *user-agent* HTTP header that identifies the device type.

ASP.NET automatically matches the supplied user-agent string with the corresponding profile specified in its database.

> **NOTE**
> This database of device capabilities is stored in a number of XML files that adhere to the Browser Definition File schema. The default device profile files are located in %WINDIR%\Microsoft.Net\Framework\v2.0.50727\CONFIG\Browsers. You can also add custom files to your application's App_Browsers folder. For more information, see How To: Detect Browser Types in ASP.NET Web Pages.

Because the default setting is UseDeviceProfile, cookieless forms authentication tickets will be used when the site is visited by a device whose profile reports that it does not support cookies.

Encoding the Authentication Ticket in the URL

Cookies are a natural medium for including information from the browser in each request to a particular website, which is why the default forms authentication settings use cookies if the visiting device supports them. If cookies are not supported, an alternate means for passing the authentication ticket from the client to the server must be employed. A common workaround used in cookieless environments is to encode the cookie data in the URL.

The best way to see how such information can be embedded within the URL is to force the site to use cookieless authentication tickets. This can be accomplished by setting the cookieless configuration setting to UseUri:

```
<authentication mode="Forms">

  <forms

  cookieless="UseUri"

  slidingExpiration="true"

  timeout="60"

  />

</authentication>
```

Once you have made this change, visit the site through a browser. When visiting as an anonymous user, the URLs will look exactly like they did before. For example, when visiting Default.aspx page my browser's address bar shows the following URL:

```
http://localhost:2448/ASPNET\_Security\_Tutorial\_03\_CS/default.aspx
```

However, upon logging in, the forms authentication ticket is embedded into the URL. For example, after visiting the login page and logging in as Sam, I am returned to the Default.aspx page, but the URL this time is:

```
http://localhost:2448/ASPNET\_Security\_Tutorial\_03\_CS/(F(jaIOIDTJxIr12xYS-VVgkqKCVAuIoW30Bu0diWi6flQC-
FyMaLXJfow\_Vd9GZkB2Cv-rfezq0gKadKX0YPZCkA2))/default.aspx
```

The forms authentication ticket has been embedded within the URL. The string (F(jaIOIDTJxIr12xYS-VVgkqKCVAuIoW30Bu0diWi6flQC-FyMaLXJfow_Vd9GZkB2Cv-rfezq0gKadKX0YPZCkA2) represents the hex-encoded authentication ticket information, and is the same data that is usually stored within a cookie.

In order for cookieless authentication tickets to work, the system must encode all URLs on the page to include the authentication ticket data, otherwise the authentication ticket will be lost when the user clicks on a link. Thankfully, this embedding logic is performed automatically. To demonstrate this functionality, open the Default.aspx page and add a HyperLink control, setting its Text and NavigateUrl properties to Test Link and SomePage.aspx, respectively. It doesn't matter that there really isn't a page in our project named SomePage.aspx.

Save the changes to Default.aspx and then visit it through a browser. Log on to the site so that the forms authentication ticket is embedded in the URL. Next, from Default.aspx, click the Test Link link. What happened? If no page named SomePage.aspx exists, then a 404 error occurred, but that's not what's important here. Instead, focus on the Address bar in your browser. Note that it includes the forms authentication ticket in the URL!

```
http://localhost:2448/ASPNET\_Security\_Tutorial\_03\_CS/(F(jaIOIDTJxIr12xYS-VVgkqKCVAuIoW30Bu0diWi6flQC-
FyMaLXJfow\_Vd9GZkB2Cv-rfezq0gKadKX0YPZCkA2))/SomePage.aspx
```

The URL SomePage.aspx in the link was automatically converted into a URL that included the authentication ticket - we didn't have to write a lick of code! The form authentication ticket will automatically be embedded in the URL for any hyperlinks that do not start with `http://` or `/`. It doesn't matter if the hyperlink appears in a call to Response.Redirect, in a HyperLink control, or in an anchor HTML element (i.e., `<a href="...">...</a>`). As long as the URL isn't something like `http://www.someserver.com/SomePage.aspx` or `/SomePage.aspx`, the forms authentication ticket will be embedded for us.

> **NOTE**
> Cookieless forms authentication tickets adhere to the same timeout policies as cookie-based authentication tickets. However, cookieless authentication tickets are more prone to replay attacks since the authentication ticket is embedded directly in the URL. Imagine a user who visits a website, logs in, and then pastes the URL in an email to a colleague. If the colleague clicks on that link before the expiry is reached, they will be logged in as the user who sent the email!

Step 3: Securing the Authentication Ticket

The forms authentication ticket is transmitted over the wire either in a cookie or embedded directly within the URL. In addition to identity information, the authentication ticket can also include user data (as we will see in Step 4). Consequently, it is important that the ticket's data is encrypted from prying eyes and (even more importantly) that the forms authentication system can guarantee that the ticket was not tampered with.

To ensure the privacy of the ticket's data, the forms authentication system can encrypt the ticket data. Failure to encrypt the ticket data sends potentially sensitive information over the wire in plain-text.

To guarantee a ticket's authenticity, the forms authentication system must *validate* the ticket. Validation is the act of ensuring that a particular piece of data has not been modified, and is accomplished via a *message authentication code (MAC)*. In a nutshell, the MAC is a small piece of information that identifies the data that needs to be validated (in this case, the ticket). If the data represented by the MAC is modified, then the MAC and the data will not match up. Moreover, it is computationally hard for a hacker to both modify the data and generate his own MAC to correspond with the modified data.

When creating (or modifying) a ticket, the forms authentication system creates a MAC and attaches it to the ticket's data. When a subsequent request arrives, the forms authentication system compares the MAC and ticket data to validate the authenticity of the ticket data. Figure 3 illustrates this workflow graphically.

Figure 03: The Ticket's Authenticity is Ensured through a MAC (Click to view full-size image)

What security measures are applied to the authentication ticket depends on the protection setting in the <forms> element. The protection setting may be assigned to one of the following three values:

- All - the ticket is both encrypted and digitally signed (the default).
- Encryption - only encryption is applied - no MAC is generated.
- None - the ticket is neither encrypted nor digitally signed.
- Validation - a MAC is generated, but the ticket data is sent over the wire in plain-text.

Microsoft strongly recommends using the All setting.

Setting the Validation and Decryption Keys

The encryption and hashing algorithms used by the forms authentication system to encrypt and validate the authentication ticket are customizable through the <machineKey> element in Web.config. Table 2 outlines the <machineKey> element's attributes and their possible values.

ATTRIBUTE	DESCRIPTION
decryption	Indicates the algorithm used for encryption. This attribute can have one of the following four values: - Auto - the default; determines the algorithm based on the length of the decryptionKey attribute. - AES - uses the Advanced Encryption Standard (AES) algorithm. - DES - uses the Data Encryption Standard (DES) This algorithm is considered computationally weak and should not be used. - 3DES - uses the Triple DES algorithm, which works by applying the DES algorithm three times.

ATTRIBUTE	DESCRIPTION
decryptionKey	The secret key used by the encryption algorithm. This value must either be a hexadecimal string of the appropriate length (based on the value in decryption), AutoGenerate, or either value appended with,IsolateApps. Adding IsolateApps instructs ASP.NET to use a unique value for each application. The default is AutoGenerate,IsolateApps.
validation	Indicates the algorithm used for validation. This attribute can have one of the following four values: - AES - uses the Advanced Encryption Standard (AES) algorithm. - MD5 - uses the Message-Digest 5 (MD5) algorithm. - SHA1 - uses the SHA1 algorithm (the default). - 3DES - uses the Triple DES algorithm.
validationKey	The secret key used by the validation algorithm. This value must either be a hexadecimal string of the appropriate length (based on the value in validation), AutoGenerate, or either value appended with,IsolateApps. Adding IsolateApps instructs ASP.NET to use a unique value for each application. The default is AutoGenerate,IsolateApps.

Table 2: The <machineKey> Element Attributes

A thorough discussion of these encryption and validation options, and the pros and cons of the various algorithms, is beyond the scope of this tutorial. For an in-depth look at these issues, including guidance on what encryption and validation algorithms to use, what key lengths to use, and how best to generate these keys, refer to *Professional ASP.NET 2.0 Security, Membership, and Role Management*.

By default, the keys used for encryption and validation are generated automatically for each application, and these keys are stored in the Local Security Authority (LSA). In short, the default settings guarantee unique keys on a web server-by-web server and application-by-application basis. Consequently, this default behavior will not work for the two following scenarios:

- **Web Farms** - in a web farm scenario, a single web application is hosted on multiple web servers for purposes of scalability and redundancy. Each incoming request is dispatched to a server in the farm, meaning that over the lifetime of a user's session, different servers may be used to handle his various requests. Consequently, each server must use the same encryption and validation keys so that the forms authentication ticket created, encrypted, and validated on one server can be decrypted and validated on a different server in the farm.
- **Cross Application Ticket Sharing** - a single web server may host multiple ASP.NET applications. If you need for these different applications to share a single forms authentication ticket, it is imperative that their encryption and validation keys match up.

When working in a web farm setting or sharing authentication tickets across applications on the same server, you will need to configure the <machineKey> element in the affected applications so that their decryptionKey and validationKey values match up.

While neither of the above scenarios applies to our sample application, we can still specify explicit decryptionKey and validationKey values and define the algorithms to be used. Add a <machineKey> setting to the Web.config file:

```
<configuration>

  <system.web>

  ... Some markup was removed for brevity ...

  <machineKey

  decryption="AES"

  validation="SHA1"

  decryptionKey="1513F567EE75F7FB5AC0AC4D79E1D9F25430E3E2F1BCDD3370BCFC4EFC97A541"

  validationKey="32CBA563F26041EE5B5FE9581076C40618DCC1218F5F447634EDE8624508A129"

  />

  </system.web>

</configuration>
```

For more information check out How To: Configure MachineKey in ASP.NET 2.0.

> **NOTE**
> The decryptionKey and validationKey values were taken from Steve Gibson's Perfect Passwords web page, which generates 64 random hexadecimal characters on each page visit. To lessen the likelihood of these keys making their way into your production applications, you are encouraged to replace the above keys with randomly generated ones from the Perfect Passwords page.

Step 4: Storing Additional User Data in the Ticket

Many web applications display information about or base the page's display on the currently logged on user. For example, a web page might show the user's name and the date she last logged on in the upper corner of every page. The forms authentication ticket stores the currently logged on user's username, but when any other information is needed, the page must go to the user store - typically a database - to lookup the information not stored in the authentication ticket.

With a little bit of code we can store additional user information in the forms authentication ticket. Such data can be expressed through the FormsAuthenticationTicket class's UserData property. This is a useful place to put small amounts of information about the user that is commonly needed. The value specified in the UserData property is included as part of the authentication ticket cookie and, like the other ticket fields, is encrypted and validated based on the forms authentication system's configuration. By default, UserData is an empty string.

In order to store user data in the authentication ticket, we need to write a bit of code in the login page that grabs the user-specific information and stores it in the ticket. Since UserData is a property of type string, the data stored in it must be properly serialized as a string. For example, imagine that our user store included each user's date of birth and the name of their employer, and we wanted to store these two property values in the authentication ticket. We could serialize these values into a string by concatenating the user's date of birth's string with a pipe (|), followed by the employer name. For a user born on August 15, 1974 that works for Northwind Traders, we would assign the UserData property the string: 1974-08-15|Northwind Traders .

Whenever we need to access the data stored in the ticket, we can do so by grabbing the current request's FormsAuthenticationTicket and deserializing the UserData property. In the case of the date of birth and employer name example, we would split the UserData string into two substrings based on the delimiter (|).

Figure 04: Additional User Information Can Be Stored in the Authentication Ticket (Click to view full-size image)

Writing Information to UserData

Unfortunately, adding user-specific information to a forms authentication ticket is not as straightforward as one might expect. The UserData property of the FormsAuthenticationTicket class is read-only and can only be specified through the FormsAuthenticationTicket class constructor. When specifying the UserData property in the constructor, we also need to provide the ticket's other values: the username, the issue date, the expiration, and so on. When we created the login page in the preceding tutorial, this was all handled for us by the FormsAuthentication class. When adding UserData to the FormsAuthenticationTicket, we will need to write code to replicate much of the functionality already provided by the FormsAuthentication class.

Let's explore the necessary code for working with UserData by updating the Login.aspx page to record additional information about the user to the authentication ticket. Pretend that our user store contains information about the company the user works for and their title, and that we want to capture this information in the authentication ticket. Update the Login.aspx page's LoginButton Click event handler so that the code looks like the following:

```
protected void LoginButton_Click(object sender, EventArgs e)

{

  // Three valid username/password pairs: Scott/password, Jisun/password, and Sam/password.

  string[] users = { "Scott", "Jisun", "Sam" };

  string[] passwords = { "password", "password", "password" };

  string[] companyName = { "Northwind Traders", "Adventure Works", "Contoso" };

  string[] titleAtCompany = { "Janitor", "Scientist", "Mascot" };

  for (int i = 0; i < users.Length; i++)

  {

  bool validUsername = (string.Compare(UserName.Text, users[i], true) == 0);

  bool validPassword = (string.Compare(Password.Text, passwords[i], false) == 0);

  if (validUsername && validPassword)

  {

  // Query the user store to get this user's User Data

  string userDataString = string.Concat(companyName[i], "|", titleAtCompany[i]);

  // Create the cookie that contains the forms authentication ticket

  HttpCookie authCookie = FormsAuthentication.GetAuthCookie(UserName.Text, RememberMe.Checked);

  // Get the FormsAuthenticationTicket out of the encrypted cookie

  FormsAuthenticationTicket ticket = FormsAuthentication.Decrypt(authCookie.Value);

  // Create a new FormsAuthenticationTicket that includes our custom User Data

  FormsAuthenticationTicket newTicket = new FormsAuthenticationTicket(ticket.Version, ticket.Name,
ticket.IssueDate, ticket.Expiration, ticket.IsPersistent, userDataString);

  // Update the authCookie's Value to use the encrypted version of newTicket

  authCookie.Value = FormsAuthentication.Encrypt(newTicket);

  // Manually add the authCookie to the Cookies collection

  Response.Cookies.Add(authCookie);

  // Determine redirect URL and send user there

  string redirUrl = FormsAuthentication.GetRedirectUrl(UserName.Text, RememberMe.Checked);

  Response.Redirect(redirUrl);

  }

  }

  // If we reach here, the user's credentials were invalid

  InvalidCredentialsMessage.Visible = true;

}
```

Let's step through this code one line at a time. The method starts by defining four string arrays: users, passwords, companyName, and titleAtCompany. These arrays hold the usernames, passwords, company names, and titles for the user accounts in the system, of which there are three: Scott, Jisun, and Sam. In a real application, these values would be queried from the user store, not hard-coded in the page's source code.

In the previous tutorial, if the supplied credentials were valid we simply called FormsAuthentication.RedirectFromLoginPage(UserName.Text, RememberMe.Checked), which performed the following steps:

1. Created the forms authentication ticket
2. Wrote the ticket to the appropriate store. For cookies-based authentication tickets, the browser's cookies collection is used; for cookieless authentication tickets, the ticket data is serialized into the URL
3. Redirected the user to the appropriate page

These steps are replicated in the code above. First, the string we will eventually store in the UserData property is formed by combining the company name and the title, delimiting the two values with a pipe character (|).

string userDataString = string.Concat(companyName[i], "|", titleAtCompany[i]);

Next, the FormsAuthentication.GetAuthCookie method is invoked, which creates the authentication ticket, encrypts and validates it according to the configuration settings, and places it in an HttpCookie object.

HttpCookie authCookie = FormsAuthentication.GetAuthCookie(UserName.Text, RememberMe.Checked);

In order to work with the FormAuthenticationTicket embedded within the cookie, we need to call the FormAuthentication class's Decrypt method, passing in the cookie value.

FormsAuthenticationTicket ticket = FormsAuthentication.Decrypt(authCookie.Value);

We then create a *new* FormsAuthenticationTicket instance based on the existing FormsAuthenticationTicket's values. However, this new ticket includes the user-specific information (userDataString).

FormsAuthenticationTicket newTicket = new FormsAuthenticationTicket(ticket.Version, ticket.Name, ticket.IssueDate, ticket.Expiration, ticket.IsPersistent, userDataString);

We then encrypt (and validate) the new FormsAuthenticationTicket instance by calling the Encrypt method, and put this encrypted (and validated) data back into authCookie.

authCookie.Value = FormsAuthentication.Encrypt(newTicket);

Finally, authCookie is added to the Response.Cookies collection and the GetRedirectUrl method is called to determine the appropriate page to send the user.

```
Response.Cookies.Add(authCookie);

string redirUrl = FormsAuthentication.GetRedirectUrl(UserName.Text, RememberMe.Checked);

Response.Redirect(redirUrl);
```

All of this code is needed because the UserData property is read-only and the FormsAuthentication class does not provide any methods for specifying UserData information in its GetAuthCookie, SetAuthCookie, or RedirectFromLoginPage methods.

> **NOTE**
> The code we just examined stores user-specific information in a cookies-based authentication ticket. The classes responsible for serializing the forms authentication ticket to the URL are internal to the .NET Framework. Long story short, you cannot store user data in a cookieless forms authentication ticket.

Accessing the UserData Information

At this point each user's company name and title is stored in the forms authentication ticket's UserData property when they log in. This information can be accessed from the authentication ticket on any page without requiring a trip to the user store. To illustrate how this information can be retrieved from the UserData property, let's update Default.aspx so that its welcome message includes not only the user's name, but also the company they work for and their title.

Currently, Default.aspx contains an AuthenticatedMessagePanel Panel with a Label control named WelcomeBackMessage. This Panel is only displayed to authenticated users. Update the code in Default.aspx's Page_Load event handler so that it looks like the following:

```
protected void Page_Load(object sender, EventArgs e)

{

  if (Request.IsAuthenticated)

  {

  WelcomeBackMessage.Text = "Welcome back, " + User.Identity.Name + "!";

  // Get User Data from FormsAuthenticationTicket and show it in WelcomeBackMessage

  FormsIdentity ident = User.Identity as FormsIdentity;

  if (ident != null)

  {

  FormsAuthenticationTicket ticket = ident.Ticket;

  string userDataString = ticket.UserData;

  // Split on the |

  string[] userDataPieces = userDataString.Split("|".ToCharArray());

  string companyName = userDataPieces[0];

  string titleAtCompany = userDataPieces[1];

  WelcomeBackMessage.Text += string.Format(" You are the {0} of {1}.", titleAtCompany, companyName);

  }

  AuthenticatedMessagePanel.Visible = true;

  AnonymousMessagePanel.Visible = false;

  }

  else

  {

  AuthenticatedMessagePanel.Visible = false;

  AnonymousMessagePanel.Visible = true;

  }

}
```

If Request.IsAuthenticated is true, then the WelcomeBackMessage's Text property is first set to Welcome back,

username. Then, the User.Identity property is cast to a FormsIdentity object so that we can access the underlying FormsAuthenticationTicket. Once we have the FormsAuthenticationTicket, we deserialize the UserData property into the company name and title. This is accomplished by splitting the string on the pipe character. The company name and title are then displayed in the WelcomeBackMessage Label.

Figure 5 shows a screenshot of this display in action. Logging in as Scott displays a welcome back message that includes Scott's company and title.

Figure 05: The Currently Logged On User's Company and Title are Displayed (Click to view full-size image)

> **NOTE**
>
> The authentication ticket's UserData property serves as a cache for the user store. Like any cache, it needs to be updated when the underlying data is modified. For example, if there is a web page from which users can update their profile, the fields cached in the UserData property must be refreshed to reflect the changes made by the user.

Step 5: Using a Custom Principal

On each incoming request the FormsAuthenticationModule attempts to authenticate the user. If a non-expired authentication ticket is present, the FormsAuthenticationModule assigns the HttpContext.User property to a new GenericPrincipal object. This GenericPrincipal object has an Identity of type FormsIdentity, which includes a reference to the forms authentication ticket. The GenericPrincipal class contains the bare minimum functionality needed by a class that implements IPrincipal - it just has an Identity property and an IsInRole method.

The principal object has two responsibilities: to indicate what roles the user belongs to and to provide identity information. This is accomplished through the IPrincipal interface's IsInRole(*roleName*) method and Identity property, respectively. The GenericPrincipal class allows for a string array of role names to be specified via its constructor; its IsInRole(*roleName*) method merely checks to see if the passed in *roleName* exists within the string array. When the FormsAuthenticationModule creates the GenericPrincipal, it passes in an empty string array to the GenericPrincipal's constructor. Consequently, any call to IsInRole will always return false.

The GenericPrincipal class meets the needs for most forms based authentication scenarios where roles are not used. For those situations where the default role handling is insufficient or when you need to associate a custom IIdentity object with the user, you can create a custom IPrincipal object during the authentication workflow and assign it to the HttpContext.User property.

> **NOTE**
>
> As we will see in future tutorials, when ASP.NET's Roles framework is enabled it creates a custom principal object of type RolePrincipal and overwrites the forms authentication-created GenericPrincipal object. It does this in order to customize the principal's IsInRole method to interface with the Roles framework's API.

Since we have not concerned ourselves with roles yet, the only reason we would have for creating a custom principal at this juncture would be to associate a custom IIdentity object to the principal. In Step 4 we looked at storing additional user information in the authentication ticket's UserData property, in particular the user's company name and their title. However, the UserData information is only accessible through the authentication ticket and only then as a serialized string, meaning that anytime we want to view the user information stored in the ticket we need to parse the UserData property.

We can improve the developer experience by creating a class that implements IIdentity and includes CompanyName and Title properties. That way, a developer can access the currently logged on user's company name and title directly through the CompanyName and Title properties without needed to know how to parse the UserData property.

Creating the Custom Identity and Principal Classes

For this tutorial, let's create the custom principal and identity objects in the App_Code folder. Start by adding an App_Code folder to your project - right-click on the project name in Solution Explorer, select the Add ASP.NET Folder option, and choose App_Code. The App_Code folder is a special ASP.NET folder that holds class files specific to the website.

> **NOTE**
>
> The App_Code folder should only be used when managing your project through the Website Project Model. If you are using the Web Application Project Model, create a standard folder and add the classes to that. For example, you could add a new folder named Classes, and place your code there.

Next, add two new class files to the App_Code folder, one named CustomIdentity.cs and one named CustomPrincipal.cs.

Figure 06: Add the CustomIdentity and CustomPrincipal Classes to Your Project (Click to view full-size image)

The CustomIdentity class is responsible for implementing the IIdentity interface, which defines the AuthenticationType, IsAuthenticated, and Name properties. In addition to those required properties, we are interested in exposing the underlying forms authentication ticket as well as properties for the user's company name and title. Enter the following code into the CustomIdentity class.

```
using System;

using System.Data;

using System.Configuration;
```

```
using System.Web;

using System.Web.Security;

using System.Web.UI;

using System.Web.UI.WebControls;

using System.Web.UI.WebControls.WebParts;

using System.Web.UI.HtmlControls;

public class CustomIdentity : System.Security.Principal.IIdentity

{

  private FormsAuthenticationTicket _ticket;

  public CustomIdentity(FormsAuthenticationTicket ticket)

  {

  _ticket = ticket;

  }

  public string AuthenticationType

  {

  get { return "Custom"; }

  }

  public bool IsAuthenticated

  {

  get { return true; }

  }

  public string Name

  {

  get { return _ticket.Name; }

  }

  public FormsAuthenticationTicket Ticket

  {

  get { return _ticket; }

  }

  public string CompanyName

  {

  get

  {

  string[] userDataPieces = _ticket.UserData.Split("|".ToCharArray());
```

```
    return userDataPieces[0];

    }

    }

    public string Title

    {

    get

    {

    string[] userDataPieces = _ticket.UserData.Split("|".ToCharArray());

    return userDataPieces[1];

    }

    }

  }
```

Note that the class includes a FormsAuthenticationTicket member variable (_ticket) and that this ticket information must be supplied through the constructor. This ticket data is used in returning the identity's Name; its UserData property is parsed to return the values for the CompanyName and Title properties.

Next, create the CustomPrincipal class. Since we are not concerned with roles at this juncture, the CustomPrincipal class's constructor accepts only a CustomIdentity object; its IsInRole method always returns false.

```
using System;

using System.Data;

using System.Configuration;

using System.Web;

using System.Web.Security;

using System.Web.UI;

using System.Web.UI.WebControls;

using System.Web.UI.WebControls.WebParts;

using System.Web.UI.HtmlControls;

public class CustomPrincipal : System.Security.Principal.IPrincipal

{

  private CustomIdentity _identity;

  public CustomPrincipal(CustomIdentity identity)

  {

  _identity = identity;

  }

  public System.Security.Principal.IIdentity Identity

  {

  get { return _identity; }

  }

  public bool IsInRole(string role)

  {

  return false;

  }

}
```

Assigning a CustomPrincipal Object to the Incoming Request's Security Context

We now have a class that extends the default IIdentity specification to include CompanyName and Title properties, as well as a custom principal class that uses the custom identity. We are ready to step into the ASP.NET pipeline and assign our custom principal object to the incoming request's security context.

The ASP.NET pipeline takes an incoming request and processes it through a number of steps. At each step, a particular event is raised, making it possible for developers to tap into the ASP.NET pipeline and modify the request at certain points in its lifecycle. The FormsAuthenticationModule, for example, waits for ASP.NET to raise the AuthenticateRequest event, at which point it inspects the incoming request for an authentication ticket. If an authentication ticket is found, a GenericPrincipal object is created and assigned to the HttpContext.User property.

After the AuthenticateRequest event, the ASP.NET pipeline raises the PostAuthenticateRequest event, which is where we can replace the GenericPrincipal object created by the FormsAuthenticationModule with an instance of

our CustomPrincipal object. Figure 7 depicts this workflow.

Figure 07: The GenericPrincipal is Replaced by a CustomPrincipal in the PostAuthenticationRequest Event (Click to view full-size image)

In order to execute code in response to an ASP.NET pipeline event, we can either create the appropriate event handler in Global.asax or create our own HTTP Module. For this tutorial let's create the event handler in Global.asax. Start by adding Global.asax to your website. Right-click on the project name in Solution Explorer and add an item of type Global Application Class named Global.asax.

Figure 08: Add a Global.asax File to Your Website (Click to view full-size image)

The default Global.asax template includes event handlers for a number of the ASP.NET pipeline events, including the Start, End and Error event, among others. Feel free to remove these event handlers, as we do not need them for this application. The event we are interested in is PostAuthenticateRequest. Update your Global.asax file so its markup looks similar to the following:

```
<%@ Application Language="C#" %>

<%@ Import Namespace="System.Security.Principal" %>

<%@ Import Namespace="System.Threading" %>

<script runat="server">

  void Application_OnPostAuthenticateRequest(object sender, EventArgs e)

  {

  // Get a reference to the current User

  IPrincipal usr = HttpContext.Current.User;

  // If we are dealing with an authenticated forms authentication request

  if (usr.Identity.IsAuthenticated && usr.Identity.AuthenticationType == "Forms")

  {

  FormsIdentity fIdent = usr.Identity as FormsIdentity;

  // Create a CustomIdentity based on the FormsAuthenticationTicket

  CustomIdentity ci = new CustomIdentity(fIdent.Ticket);

  // Create the CustomPrincipal

  CustomPrincipal p = new CustomPrincipal(ci);

  // Attach the CustomPrincipal to HttpContext.User and Thread.CurrentPrincipal

  HttpContext.Current.User = p;

  Thread.CurrentPrincipal = p;

  }

  }

</script>
```

The Application_OnPostAuthenticateRequest method executes each time the ASP.NET runtime raises the PostAuthenticateRequest event, which happens once on each incoming page request. The event handler starts by checking to see if the user is authenticated and was authenticated via forms authentication. If so, a new CustomIdentity object is created and passed the current request's authentication ticket in its constructor. Following that, a CustomPrincipal object is created and passed the just-created CustomIdentity object in its constructor. Finally, the current request's security context is assigned to the newly created CustomPrincipal object.

Note that the last step - associating the CustomPrincipal object with the request's security context - assigns the principal to two properties: HttpContext.User and Thread.CurrentPrincipal. These two assignments are necessary because of the way security contexts are handled in ASP.NET. The .NET Framework associates a security context with each running thread; this information is available as an IPrincipal object through the Thread object's CurrentPrincipal property. What is a confusing is that ASP.NET has its own security context information (HttpContext.User).

In certain scenarios, the Thread.CurrentPrincipal property is examined when determining the security context; in other scenarios, HttpContext.User is used. For example, there are security features in .NET that allow developers to declaratively state what users or roles can instantiate a class or invoke specific methods (see Adding

Authorization Rules to Business and Data Layers Using PrincipalPermissionAttributes). Underneath the covers, these declarative techniques determine the security context via the Thread.CurrentPrincipal property.

In other scenarios, the HttpContext.User property is used. For example, in the previous tutorial we used this property to display the currently logged on user's username. Clearly, then, it is imperative that the security context information in the Thread.CurrentPrincipal and HttpContext.User properties match up.

The ASP.NET runtime automatically syncs these property values for us. However, this synchronization occurs after the AuthenticateRequest event, but *before* the PostAuthenticateRequest event. Consequently, when adding a custom principal in the PostAuthenticateRequest event we need to be certain to manually assign the Thread.CurrentPrincipal or else Thread.CurrentPrincipal and HttpContext.User will be out of sync. See Context.User vs. Thread.CurrentPrincipal for a more detailed discussion on this issue.

Accessing the CompanyName and Title Properties

Whenever a request arrives and is dispatched to the ASP.NET engine, the Application_OnPostAuthenticateRequest event handler in Global.asax will fire. If the request has been successfully authenticated by the FormsAuthenticationModule, the event handler will create a new CustomPrincipal object with a CustomIdentity object based on the forms authentication ticket. With this logic in place, accessing information about the currently logged on user's company name and title is incredibly straightforward.

Return to the Page_Load event handler in Default.aspx, where in Step 4 we wrote code to retrieve the form authentication ticket and parse the UserData property in order to display the user's company name and title. With the CustomPrincipal and CustomIdentity objects in use now, there's no need to parse the values out of the ticket's UserData property. Instead, simply get a reference to the CustomIdentity object and use its CompanyName and Title properties:

```
CustomIdentity ident = User.Identity as CustomIdentity;

if (ident != null)

  WelcomeBackMessage.Text += string.Format(" You are the {0} of {1}.", ident.Title, ident.CompanyName);
```

Summary

In this tutorial we examined how to customize the forms authentication system's settings via Web.config. We looked at how the authentication ticket's expiration is handled and how the encryption and validation safeguards are used to protect the ticket from inspection and modification. Finally, we discussed using the authentication ticket's UserData property to store additional user information in the ticket itself, and how to use custom principal and identity objects to expose this information in a more developer-friendly manner.

This tutorial concludes our examination of forms authentication in ASP.NET. The next tutorial starts our journey into the Membership framework.

Happy Programming!

Security Basics and ASP.NET Support (VB)

2/20/2020 • 16 minutes to read • Edit Online

by Scott Mitchell

Download PDF

This is the first tutorial in a series of tutorials that will explore techniques for authenticating visitors through a web form, authorizing access to particular pages and functionality, and managing user accounts in an ASP.NET application.

Introduction

What is the one thing forums, eCommerce sites, online email websites, portal websites, and social network sites all have in common? They all offer *user accounts*. Sites that offer user accounts must provide a number of services. At a minimum, new visitors need to be able to create an account and returning visitors must be able to log in. Such web applications can make decisions based on the logged in user: some pages or actions might be restricted to only logged in users, or to a certain subset of users; other pages might show information specific to the logged in user, or might show more or less information, depending on what user is viewing the page.

This is the first tutorial in a series of tutorials that will explore techniques for authenticating visitors through a web form, authorizing access to particular pages and functionality, and managing user accounts in an ASP.NET application. Over the course of these tutorials we will examine how to:

- Identify and log users in to a website
- Use ASP.NET's Membership framework to manage user accounts
- Create, update, and delete user accounts
- Limit access to a web page, directory, or specific functionality based on the logged in user
- Use ASP.NET's Roles framework to associate user accounts with roles
- Manage user roles
- Limit access to a web page, directory, or specific functionality based on the logged in user's role
- Customize and extend ASP.NET's security Web controls

These tutorials are geared to be concise and provide step-by-step instructions with plenty of screen shots to walk you through the process visually. Each tutorial is available in C# and Visual Basic versions and includes a download of the complete code used. (This first tutorial focuses on security concepts from a high-level viewpoint and therefore does not contain any associated code.)

In this tutorial we will discuss important security concepts and what facilities are available in ASP.NET to assist in implementing forms authentication, authorization, user accounts, and roles. Let's get started!

> **NOTE**
>
> Security is an important aspect of any application that spans physical, technological, and policy decisions and requires a high degree of planning and domain knowledge. This tutorial series is not intended as a guide for developing secure web applications. Rather, it focuses specifically on forms authentication, authorization, user accounts, and roles. While some security concepts revolving around these issues are discussed in this series, others are left unexplored.

Authentication, Authorization, User Accounts, and Roles

Authentication, authorization, user accounts, and roles are four terms that will be used very often throughout this tutorial series, so I'd like to take a quick moment to define these terms within the context of web security. In a client-server model, such as the Internet, there are many scenarios in which the server needs to identify the client making the request. *Authentication* is the process of ascertaining the client's identity. A client who has been successfully identified is said to be *authenticated*. An unidentified client is said to be *unauthenticated* or *anonymous*.

Secure authentication systems involve at least one of the following three facets: something you know, something you have, or something you are. Most web applications rely on something the client knows, such as a password or a PIN. The information used to identify a user - her username and password, for example - are referred to as *credentials*. This tutorial series focuses on *forms authentication*, which is an authentication model where users log in to the site by providing their credentials in a web page form. We have all experienced this type of authentication before. Go to any eCommerce site. When you are ready to check out you are asked to log in by entering your username and password into textboxes on a web page.

In addition to identifying clients, a server may need to limit what resources or functionalities are accessible depending on the client making the request. *Authorization* is the process of determining whether a particular user has the authority to access a specific resource or functionality.

A *user account* is a store for persisting information about a particular user. User accounts must minimally include information that uniquely identifies the user, such as the user's login name and password. Along with this essential information, user accounts may include things like: the user's email address; the date and time the account was created; the date and time they last logged in; first and last name; phone number; and mailing address. When using forms authentication, user account information is typically stored in a relational database like Microsoft SQL Server.

Web applications that support user accounts may optionally group users into *roles*. A role is simply a label that is applied to a user and provides an abstraction for defining authorization rules and page-level functionality. For example, a website might include an Administrator role with authorization rules that prohibit anyone but an Administrator to access a particular set of web pages. Moreover, a variety of pages that are accessible to all users (including non-Administrators) might display additional data or offer extra functionality when visited by users in the Administrators role. Using roles, we can define these authorization rules on a role-by-role basis rather than user-by-user.

Authenticating Users in an ASP.NET Application

When a user enters a URL into their browser's address window or clicks on a link, the browser makes a Hypertext Transfer Protocol (HTTP) request to the web server for the specified content, be it an ASP.NET page, an image, a JavaScript file, or any other type of content. The web server is tasked with returning the requested content. In doing so, it must determine a number of things about the request, including who made the request and whether the identity is authorized to retrieve the requested content.

By default, browsers send HTTP requests that lack any sort of identification information. But if the browser does include authentication information then the web server starts the authentication workflow, which attempts to identify the client making the request. The steps of the authentication workflow depend on the type of authentication being used by the web application. ASP.NET supports three types of authentication: Windows, Passport, and forms. This tutorial series focuses on forms authentication, but let's take a minute to compare and contrast Windows authentication user stores and workflow.

Authentication via Windows Authentication

The Windows authentication workflow uses one of the following authentication techniques:

- Basic authentication
- Digest authentication
- Windows Integrated Authentication

All three techniques work in roughly the same way: when an unauthorized, anonymous request arrives, the web server sends back an HTTP response that indicates that authorization is required to continue. The browser then displays a modal dialog box that prompts the user for their username and password (see Figure 1). This information is then sent back to the web server via an HTTP header.

Figure 1: A Modal Dialog Box Prompts the User for His Credentials

The supplied credentials are validated against the web server's Windows User Store. This means that each authenticated user in your web application must have a Windows account in your organization. This is commonplace in intranet scenarios. In fact, when using Windows Integrated Authentication in an intranet setting, the browser automatically provides the web server with the credentials used to log on to the network, thereby suppressing the dialog box shown in Figure 1. While Windows authentication is great for intranet applications, it is usually unfeasible for Internet applications since you do not want to create Windows accounts for each and every user who signs up at your site.

Authentication via Forms Authentication

Forms authentication, on the other hand, is ideal for Internet web applications. Recall that forms authentication identifies the user by prompting them to enter their credentials through a web form. Consequently, when a user attempts to access an unauthorized resource, they are automatically redirected to the login page where they can enter their credentials. The submitted credentials are then validated against a custom user store - usually a database.

After verifying the submitted credentials, a *forms authentication ticket* is created for the user. This ticket indicates that the user has been authenticated and includes identifying information, such as the username. The forms authentication ticket is (typically) stored as a cookie on the client computer. Therefore, subsequent visits to the website include the forms authentication ticket in the HTTP request, thereby enabling the web application to identify the user once they have logged in.

Figure 2 illustrates the forms authentication workflow from a high-level vantage point. Notice how the authentication and authorization pieces in ASP.NET act as two separate entities. The forms authentication system identifies the user (or reports that they are anonymous). The authorization system is what determines whether the user has access to the requested resource. If the user is unauthorized (as they are in Figure 2 when attempting to anonymously visit ProtectedPage.aspx), the authorization system reports that the user is denied, causing the forms authentication system to automatically redirect the user to the login page.

Once the user has successfully logged in, subsequent HTTP requests include the forms authentication ticket. The forms authentication system merely identifies the user - it is the authorization system that determines whether the user can access the requested resource.

Figure 2: The Forms Authentication Workflow

We will dig into forms authentication in much greater detail in the next two tutorials,An Overview of Forms Authentication and Forms Authentication Configuration and Advanced Topics. For more on ASP.NET's authentication options, see ASP.NET Authentication.

Limiting Access to Web Pages, Directories, and Page Functionality

ASP.NET includes two ways to determine whether a particular user has authority to access a specific file or directory:

- **File authorization** - since ASP.NET pages and web services are implemented as files that reside on the web server's file system, access to these files can be specified through Access Control Lists (ACLs). File authorization is most commonly used with Windows authentication because ACLs are permissions that apply to Windows accounts. When using forms authentication, all operating system- and file system-level requests are executed by the same Windows account, regardless of the user visiting the site.
- **URL authorization**- with URL authorization, the page developer specifies authorization rules in Web.config. These authorization rules specify what users or roles are allowed to access or are denied from accessing certain pages or directories in the application.

File authorization and URL authorization define authorization rules for accessing a particular ASP.NET page or for all ASP.NET pages in a particular directory. Using these techniques we can instruct ASP.NET to deny requests to a particular page for a particular user, or allow access to a set of users and deny access to everyone else. What about scenarios where all of the users can access the page, but the page's functionality depends on the user? For example, many sites that support user accounts have pages that display different content or data for authenticated users versus anonymous users. An anonymous user might see a link to log in to the site, whereas an authenticated user would instead see a message like, Welcome back, *Username* along with a link to log out. Another example: when viewing an item at an auction site you see different information depending on whether you are a bidder or the one auctioning the item.

Such page-level adjustments can be accomplished declaratively or programmatically. To show different content for anonymous than authenticated users, simply drag a LoginView control onto your page and enter the appropriate content into its AnonymousTemplate and LoggedInTemplate templates. Alternatively, you can programmatically determine whether the current request is authenticated, who the user is, and what roles they belong to (if any). You can use this information to then show or hide columns in a grid or Panels on the page.

This series includes three tutorials that focus on authorization. ***User-Based Authorization***examines how to limit access to a page or pages in a directory for specific user accounts; ***Role-Based Authorization*** looks at supplying authorization rules at the role level; lastly, the ***Displaying Content Based on the Currently Logged In User*** tutorial explores modifying a particular page's content and functionality based on the user visiting the page. For more on ASP.NET's authorization options, see ASP.NET Authorization.

User Accounts and Roles

ASP.NET's forms authentication provides an infrastructure for users to log in to a site and have their authenticated state remembered across page visits. And URL authorization offers a framework for limiting access to specific files or folders in an ASP.NET application. Neither feature, however, supplies a means for storing user account information or managing roles.

Prior to ASP.NET 2.0, developers were responsible for creating their own user and role stores. They were also on the hook for designing the user interfaces and writing the code for essential user account-related pages like the login page and the page to create a new account, among others. Without any built-in user account framework in ASP.NET, each developer implementing user accounts had to arrive at his own design decisions on questions like, How do I store passwords or other sensitive information? and What guidelines should I impose regarding password length and strength?

Today, implementing user accounts in an ASP.NET application is much simpler thanks to the *Membership framework* and the built-in Login Web controls. The Membership framework is a handful of classes in the System.Web.Security namespace that provide functionality for performing essential user account-related tasks. The key class in the Membership framework is the Membership class, which has methods like:

- CreateUser
- DeleteUser
- GetAllUsers
- GetUser
- UpdateUser
- ValidateUser

The Membership framework uses the provider model, which cleanly separates the Membership framework's API from its implementation. This enables developers to use a common API, but empowers them to use an implementation that meets their application's custom needs. In short, the Membership class defines the essential functionality of the framework (the methods, properties, and events), but does not actually supply any implementation details. Instead, the methods of the Membership class invoke the configured provider, which is what performs the actual work. For example, when the Membership class's CreateUser method is invoked, the Membership class doesn't know the details of the user store. It doesn't know if users are being maintained in a database or in an XML file or in some other store. The Membership class examines the web application's configuration to determine what provider to delegate the call to, and that provider class is responsible for actually creating the new user account in the appropriate user store. This interaction is illustrated in Figure 3.

Microsoft ships two Membership provider classes in the .NET Framework:

- ActiveDirectoryMembershipProvider - implements the Membership API in Active Directory and Active Directory Application Mode (ADAM) servers.
- SqlMembershipProvider - implements the Membership API in a SQL Server database.

This tutorial series focuses exclusively on the SqlMembershipProvider.

Figure 03: The Provider Model Enables Different Implementations to be Seamlessly Plugged Into the Framework (Click to view full-size image)

The benefit of the provider model is that alternative implementations can be developed by Microsoft, third-party vendors, or individual developers and seamlessly plugged into the Membership framework. For example, Microsoft has released a Membership provider for Microsoft Access databases. For more information on the Membership providers, refer to the Provider Toolkit, which includes a walkthrough of the Membership providers, sample custom providers, over 100 pages of documentation on the provider model, and the complete source code for the built-in Membership providers (namely, ActiveDirectoryMembershipProvider and SqlMembershipProvider).

ASP.NET 2.0 also introduced the Roles framework. Like the Membership framework, the Roles framework is built atop the provider model. Its API is exposed via the Roles class and the .NET Framework ships with three provider classes:

- AuthorizationStoreRoleProvider - manages role information in an authorization-manager policy store, such as Active Directory or ADAM.
- SqlRoleProvider - implements roles in a SQL Server database.
- WindowsTokenRoleProvider - associates role information based on the visitor's Windows group. This method is typically used with Windows authentication.

This tutorial series focuses exclusively on the SqlRoleProvider.

Since the provider model includes a single forward-facing API (the Membership and Roles classes), it is possible to build functionality around that API without having to worry about the implementation details - those are handled by the providers selected by the page developer. This unified API allows for Microsoft and third-party vendors to build Web controls that interface with the Membership and Roles frameworks. ASP.NET ships with a number of Login Web controls for implementing common user account user interfaces. For example, the Login control prompts a user for their credentials, validates them, and then logs them in via forms authentication. The LoginView control offers templates for displaying different markup to anonymous users versus authenticated

users, or different markup based on the user's role. And the CreateUserWizard control provides a step-by-step user interface for creating a new user account.

Underneath the covers the various Login controls interact with the Membership and Roles frameworks. Most Login controls can be implemented without having to write a single line of code. We will examine these controls in greater detail in future tutorials, including techniques for extending and customizing their functionality.

Summary

All web applications that support user accounts require similar features, such as: the ability for users to log in and have their log in status remembered across page visits; a web page for new visitors to create an account; and the ability to the page developer to specify what resource, data, and functionality are available to what users or roles. The tasks of authenticating and authorizing users and of managing user accounts and roles is remarkably easy to accomplish in ASP.NET applications thanks to forms authentication, URL authorization, and the Membership and Roles frameworks.

Over the course of the next several tutorials we will examine these aspects by building a working web application from the ground up in a step-by-step fashion. In the next two tutorial we will explore forms authentication in detail. We will see the forms authentication workflow in action, dissect the forms authentication ticket, discuss security concerns, and see how to configure the forms authentication system - all while building a web application that allows visitors to log in and log out.

Happy Programming!

> In this tutorial we will turn from mere discussion to implementation; in particular, we will look at implementing forms authentication. The web application we start constructing in this tutorial will continue to be built upon in subsequent tutorials, as we move from simple forms authentication to membership and roles.
>
> Please see this video for more information on this topic: Using Basic Forms Authentication in ASP.NET.

Introduction

In the preceding tutorial we discussed the various authentication, authorization, and user account options provided by ASP.NET. In this tutorial we will turn from mere discussion to implementation; in particular, we will look at implementing forms authentication. The web application we start constructing in this tutorial will continue to be built upon in subsequent tutorials, as we move from simple forms authentication to membership and roles.

This tutorial begins with an in-depth look at the forms authentication workflow, a topic we touched upon in the previous tutorial. Following that, we will create an ASP.NET website through which to demo the concepts of forms authentication. Next, we will configure the site to use forms authentication, create a simple login page, and see how to determine, in code, whether a user is authenticated and, if so, the username they logged in with.

Understanding the forms authentication workflow, enabling it in a web application, and creating the login and logoff pages are all vital steps in building an ASP.NET application that supports user accounts and authenticates users through a web page. Because of this - and because these tutorials build upon one another - I would encourage you to work through this tutorial in full before moving on to the next one even if you already have had experience configuring forms authentication in past projects.

Understanding the Forms Authentication Workflow

When the ASP.NET runtime processes a request for an ASP.NET resource, such as an ASP.NET page or ASP.NET Web service, the request raises a number of events during its lifecycle. There are events raised at the very beginning and very end of the request, ones raised when the request is being authenticated and authorized, an event raised in the case of an unhandled exception, and so forth. To see a complete listing of the events, refer to the HttpApplication object's events.

HTTP Modules are managed classes whose code is executed in response to a particular event in the request lifecycle. ASP.NET ships with a number of HTTP Modules that perform essential tasks behind the scenes. Two built-in HTTP Modules that are especially relevant to our discussion are:

- **FormsAuthenticationModule** - authenticates the user by inspecting the forms authentication ticket, which is typically included in the user's cookies collection. If no forms authentication ticket is present, the user is anonymous.
- **UrlAuthorizationModule** - determines whether or not the current user is authorized to access the requested URL. This module determines the authority by consulting the authorization rules specified in the application's configuration files. ASP.NET also includes the FileAuthorizationModule that determines authority

by consulting the requested file(s) ACLs.

The FormsAuthenticationModule attempts to authenticate the user prior to the UrlAuthorizationModule (and FileAuthorizationModule) executing. If the user making the request is not authorized to access the requested resource, the authorization module terminates the request and returns an HTTP 401 Unauthorized status. In Windows authentication scenarios, the HTTP 401 status is returned to the browser. This status code causes the browser to prompt the user for their credentials via a modal dialog box. With forms authentication, however, the HTTP 401 Unauthorized status is never sent to the browser because the FormsAuthenticationModule detects this status and modifies it to redirect the user to the login page instead (via an HTTP 302 Redirect status).

The login page's responsibility is to determine if the user's credentials are valid and, if so, to create a forms authentication ticket and redirect the user back to the page they were attempting to visit. The authentication ticket is included in subsequent requests to the pages on the website, which the FormsAuthenticationModule uses to identify the user.

Figure 01: The Forms Authentication Workflow(Click to view full-size image)

Remembering the Authentication Ticket Across Page Visits

After logging in, the forms authentication ticket must be sent back to the web server on each request so that the user remains logged in as they browse the site. This is typically accomplished by placing the authentication ticket in the user's cookies collection. Cookies are small text files that reside on the user's computer and are transmitted in the HTTP headers on each request to the website that created the cookie. Therefore, once the forms authentication ticket has been created and stored in the browser's cookies, each subsequent visit to that site sends the authentication ticket along with the request, thereby identifying the user.

NOTE

The demo web application used in each tutorial is available as a download. This downloadable application was created with Visual Web Developer 2008 targeted for the .NET Framework version 3.5. Since the application is targeted for .NET 3.5, its Web.config file includes additional, 3.5-specific configuration elements. Long story short, if you have yet to install .NET 3.5 on your computer then the downloadable web application will not work without first removing the 3.5-specific markup from Web.config.

One aspect of cookies is their expiration, which is the date and time at which the browser discards the cookie. When the forms authentication cookie expires, the user can no longer be authenticated and therefore become anonymous. When a user is visiting from a public terminal, chances are they want their authentication ticket to expire when they close their browser. When visiting from home, however, that same user might want the authentication ticket to be remembered across browser restarts so that they do not have to re-log in each time they visit the site. This decision is often made by the user in the form of a Remember me checkbox on the login page. In Step 3 we will examine how to implement a Remember me checkbox in the login page. The following tutorial addresses the authentication ticket timeout settings in detail.

NOTE

It is possible that the user agent used to log on to the website may not support cookies. In such a case, ASP.NET can use cookieless forms authentication tickets. In this mode, the authentication ticket is encoded into the URL. We will look at when cookieless authentication tickets are used and how they are created and managed in the next tutorial.

The Scope of Forms Authentication

The FormsAuthenticationModule is managed code that is part of the ASP.NET runtime. Prior to version 7 of Microsoft's Internet Information Services (IIS) web server, there was a distinct barrier between IIS's HTTP pipeline and the ASP.NET runtime's pipeline. In short, in IIS 6 and earlier, the FormsAuthenticationModule only executes when a request is delegated from IIS to the ASP.NET runtime. By default, IIS processes static content itself - like HTML pages and CSS and image files - and only hands off requests to the ASP.NET runtime when a page with an extension of .aspx, .asmx, or .ashx is requested.

IIS 7, however, allows for integrated IIS and ASP.NET pipelines. With a few configuration settings you can setup IIS 7 to invoke the FormsAuthenticationModule for *all* requests. Furthermore, with IIS 7 you can define URL authorization rules for files of any type. For more information, see Changes Between IIS6 and IIS7 Security, Your Web Platform Security, and Understanding IIS7 URL Authorization.

Long story short, in versions prior to IIS 7, you can only use forms authentication to protect resources handled by the ASP.NET runtime. Likewise, URL authorization rules are only applied to resources handled by the ASP.NET runtime. But with IIS 7 it is possible to integrate the FormsAuthenticationModule and UrlAuthorizationModule into IIS's HTTP pipeline, thereby extending this functionality to all requests.

Step 1: Creating an ASP.NET Website for this Tutorial Series

In order to reach the widest possible audience, the ASP.NET website we will be building throughout this series will be created with Microsoft's free version of Visual Studio 2008, Visual Web Developer 2008. We will implement the SqlMembershipProvider user store in a Microsoft SQL Server 2005 Express Edition database. If you are using Visual Studio 2005 or a different edition of Visual Studio 2008 or SQL Server, don't worry - the steps will be nearly identical and any non-trivial differences will be pointed out.

Before we can configure forms authentication, we first need an ASP.NET website. Start by creating a new file system-based ASP.NET website. To accomplish this, launch Visual Web Developer and then go to the File menu and choose New Web Site, displaying the New Web Site dialog box. Choose the ASP.NET Web Site template, set the Location drop-down list to File System, choose a folder to place the web site, and set the language to VB.

This will create a new web site with a Default.aspx ASP.NET page, an App_Data folder, and a Web.config file.

> **NOTE**
>
> Visual Studio supports two modes of project management: Web Site Projects and Web Application Projects. Web Site Projects lack a project file, whereas Web Application Projects mimic the project architecture in Visual Studio .NET 2002/2003 - they include a project file and compile the project's source code into a single assembly, which is placed in the /bin folder. Visual Studio 2005 initially only supported Web Site Projects, although the Web Application Project model was reintroduced with Service Pack 1; Visual Studio 2008 offers both project models. The Visual Web Developer 2005 and 2008 editions, however, only support Web Site Projects. I will be using the Web Site Project model. If you are using a non-Express edition and want to use the Web Application Project model instead, feel free to do so but be aware that there may be some discrepancies between what you see on your screen and the steps you must take versus the screen shots shown and instructions provided in these tutorials.

Figure 02: Create a New File System-Based Web Site(Click to view full-size image)

Adding a Master Page

Next, add a new Master Page to the site in the root directory named Site.master. Master pages enable a page developer to define a site-wide template that can be applied to ASP.NET pages. The main benefit of master pages is that the site's overall appearance can be defined in a single location, thereby making it easy to update or tweak the site's layout.

Figure 03: Add a Master Page Named Site.master to the Website(Click to view full-size image)

Define the site-wide page layout here in the master page. You can use the Design view and add whatever Layout or Web controls you need, or you can manually add the markup by hand in the Source view. I structured my master page's layout to mimic the layout used in my *Working with Data in ASP.NET 2.0* tutorial series (see Figure 4). The master page uses cascading style sheets for positioning and styles with the CSS settings defined in the file Style.css (which is included in this tutorial's associated download). While you cannot tell from the markup shown below, the CSS rules are defined such that the navigation 's content is absolutely positioned so that it appears on the left and has a fixed width of 200 pixels.

```
<%@ Master Language="VB" CodeFile="Site.master.vb" Inherits="Site" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
 <head id="Head1" runat="server">
 <title>Forms Authentication, Authorization, and User Accounts</title>
 <link href="Styles.css" rel="stylesheet" type="text/css" />
 </head>
 <body>
 <div id="wrapper">
 <form id="form1" runat="server">
 <div id="header">
 <span class="title">User Account Tutorials</span>
 </div>
 <div id="content">
 <asp:contentplaceholder id="MainContent" runat="server">
 <!-- Page-specific content will go here... -->
 </asp:contentplaceholder>
 </div>
 <div id="navigation">
 TODO: Menu will go here...
 </div>
 </form>
 </div>
 </body>
</html>
```

A master page defines both the static page layout and the regions that can be edited by the ASP.NET pages that use the master page. These content editable regions are indicated by the ContentPlaceHolder control, which can be seen within the content . Our master page has a single ContentPlaceHolder (MainContent), but master page's may have multiple ContentPlaceHolders.

With the markup entered above, switching to the Design view shows the master page's layout. Any ASP.NET pages that use this master page will have this uniform layout, with the ability to specify the markup for the MainContent region.

Figure 04:The Master Page, When Viewed Through the Design View(Click to view full-size image)

Creating Content Pages

At this point we have a Default.aspx page in our website, but it does not use the master page we just created. While it is possible to manipulate the declarative markup of a web page to use a master page, if the page doesn't contain any content yet it is easier to just delete the page and re-add it to the project, specifying the master page to use. Therefore, start by deleting Default.aspx from the project.

Next, right-click on the project name in the Solution Explorer and choose to add a new Web Form named Default.aspx. This time, check the Select master page checkbox and choose the Site.master master page from the list.

Figure 05: Add a New Default.aspx Page Choosing to Select a Master Page(Click to view full-size image)

Figure 06: Use the Site.master Master Page(Click to view full-size image)

> **NOTE**
> If you are using the Web Application Project Model the Add New Item dialog box does not include a Select master page checkbox. Instead, you need to add an item of type Web Content Form. After choosing the Web Content Form option and clicking Add, Visual Studio will display the same Select a Master dialog box shown in Figure 6.

The new Default.aspx page's declarative markup includes just a @Page directive specifying the path to the master page file and a Content control for the master page's MainContent ContentPlaceHolder.

```
<%@ Page Language="VB" MasterPageFile="~/Site.master" AutoEventWireup="false" CodeFile="Default.aspx.vb"
Inherits="_Default" Title="Untitled Page" %>
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
</asp:Content>
```

For now, leave Default.aspx empty. We will return to it later in this tutorial to add content.

> **NOTE**
> Our master page includes a section for a menu or some other navigation interface. We will create such an interface in a future tutorial.

Step 2: Enabling Forms Authentication

With the ASP.NET website created, our next task is to enable forms authentication. The application's authentication configuration is specified through the <authentication> element in Web.config. The <authentication> element contains a single attribute named mode that specifies the authentication model used by the application. This attribute can have one of the following four values:

- **Windows** - as discussed in the preceding tutorial, when an application uses Windows authentication it is the web server's responsibility to authenticate the visitor, and this is usually done through Basic, Digest, or Integrated Windows authentication.
- **Forms**- users are authenticated via a form on a web page.
- **Passport**- users are authenticated using Microsoft's Passport Network.
- **None**- no authentication model is used; all visitors are anonymous.

By default, ASP.NET applications use Windows authentication. To change the authentication type to forms

authentication, then, we need to modify the <authentication> element's mode attribute to Forms.

If your project does not yet contain a Web.config file, add one now by right-clicking on the project name in the Solution Explorer, choosing Add New Item, and then adding a Web Configuration file.

Figure 07: If Your Project Does Not Yet Include Web.config, Add It Now(Click to view full-size image)

Next, locate the <authentication> element and update it to use forms authentication. After this change, your Web.config file's markup should look similar to the following:

```
<configuration>
 <system.web>
 ... Unrelated configuration settings and comments removed for brevity ...
 <!--
 The <authentication> section enables configuration
 of the security authentication mode used by
 ASP.NET to identify an incoming user.
 -->
 <authentication mode="Forms" />
 </system.web>
</configuration>
```

> **NOTE**
> Since Web.config is an XML file, casing is important. Make sure that you set the mode attribute to Forms, with a capital F. If you use a different casing, such as forms, you'll receive a configuration error when visiting the site through a browser.

The <authentication> element may optionally include a <forms> child element that contains forms authentication-specific settings. For now, let's just use the default forms authentication settings. We will explore the <forms> child element in more detail in the next tutorial.

Step 3: Building the Login Page

In order to support forms authentication our website needs a login page. As discussed in the Understanding the Forms Authentication Workflow section, the FormsAuthenticationModule will automatically redirect the user to the login page if they attempt to access a page that they are not authorized to view. There are also ASP.NET Web controls that will display a link to the login page to anonymous users. This begs the question, What is the URL of the login page?

By default, the forms authentication system expects the login page to be named Login.aspx and placed in the

root directory of the web application. If you want to use a different login page URL, you can do so by specifying it in Web.config. We will see how to do this in the subsequent tutorial.

The login page has three responsibilities:

1. Provide an interface that allows the visitor to enter their credentials.
2. Determine if the submitted credentials are valid.
3. Log in the user by creating the forms authentication ticket.

Creating the Login Page's User Interface

Let's get started with the first task. Add a new ASP.NET page to the site's root directory named Login.aspx and associate it with the Site.master master page.

Figure 08: Add a New ASP.NET Page Named Login.aspx(Click to view full-size image)

The typical login page interface consists of two textboxes - one for the user's name, one for their password - and a button to submit the form. Websites oftentimes include a Remember me checkbox that, if checked, persists the resulting authentication ticket across browser restarts.

Add two TextBoxes to Login.aspx and set their ID properties to UserName and Password, respectively. Also set Password's TextMode property to Password. Next, add a CheckBox control, setting its ID property to RememberMe and its Text property to Remember Me. Following that, add a Button named LoginButton whose Text property is set to Login. And finally, add a Label Web control and set its ID property to InvalidCredentialsMessage, its Text property to Your username or password is invalid. Please try again., its ForeColor property to Red, and its Visible property to False.

At this point your screen should look similar to the screen shot in Figure 9, and your page's declarative syntax should like the following:

```
<%@ Page Language="VB" MasterPageFile="~/Site.master" AutoEventWireup="false" CodeFile="Login.aspx.vb"
Inherits="Login" %>
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
 <h1>
 Login
 </h1>
 <p>
 Username: <asp:TextBox ID="UserName" runat="server"></asp:TextBox>
 </p>
 <p>
 Password: <asp:TextBox ID="Password" runat="server" TextMode="Password"></asp:TextBox>
 </p>
 <p>
 <asp:CheckBox ID="RememberMe" runat="server" Text="Remember Me" />
 </p>
 <p>
 <asp:Button ID="LoginButton" runat="server" Text="Login" OnClick="LoginButton_Click" />
 </p>
 <p>
 <asp:Label ID="InvalidCredentialsMessage" runat="server" ForeColor="Red" Text="Your username or password
is invalid. Please try again."
 Visible="False"></asp:Label>
 </p>
</asp:Content>
```

Figure 09: The Login Page Contains Two TextBoxes, a CheckBox, a Button, and a Label(Click to view full-size image)

Finally, create an event handler for the LoginButton's Click event. From the Designer, simply double-click the Button control to create this event handler.

Determining If the Supplied Credentials are Valid

We now need to implement task 2 in the Button's Click event handler - determining whether the supplied credentials are valid. In order to do this there needs to be a user store that holds all of the users' credentials so that we can determine if the supplied credentials match up with any known credentials.

Prior to ASP.NET 2.0, developers were responsible for implementing both their own user stores and writing the code to validate the supplied credentials against the store. Most developers would implement the user store in a database, creating a table named Users with columns like UserName, Password, Email, LastLoginDate, and so forth. This table, then, would have one record per user account. Verifying a user's supplied credentials would involve querying the database for a matching username and then ensuring that the password in the database corresponded to the supplied password.

With ASP.NET 2.0, developers should use one of the Membership providers to manage the user store. In this tutorial series we will be using the SqlMembershipProvider, which uses a SQL Server database for the user store. When using the SqlMembershipProvider we need to implement a specific database schema that includes the tables, views, and stored procedures expected by the provider. We will examine how to implement this schema in the *Creating the Membership Schema in SQL Server* tutorial. With the Membership provider in place, validating the user's credentials is as simple as calling the Membership class's ValidateUser(*username*, *password*) method, which returns a Boolean value indicating whether the validity of the *username* and *password* combination. Seeing as we have not yet implemented the SqlMembershipProvider's user store, we cannot use the Membership class's ValidateUser method at this time.

Rather than take the time to build our own custom Users database table (which would be obsolete once we implemented the SqlMembershipProvider), let's instead hard-code the valid credentials within the login page itself. In the LoginButton's Click event handler, add the following code:

```
Protected Sub LoginButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
LoginButton.Click
 ' Three valid username/password pairs: Scott/password, Jisun/password, and Sam/password.
 Dim users() As String = {"Scott", "Jisun", "Sam"}
 Dim passwords() As String = {"password", "password", "password"}
 For i As Integer = 0 To users.Length - 1
 Dim validUsername As Boolean = (String.Compare(UserName.Text, users(i), True) = 0)
 Dim validPassword As Boolean = (String.Compare(Password.Text, passwords(i), False) = 0)
 If validUsername AndAlso validPassword Then
 ' TODO: Log in the user...
 ' TODO: Redirect them to the appropriate page
 End If
 Next
 ' If we reach here, the user's credentials were invalid
 InvalidCredentialsMessage.Visible = True
End Sub
```

As you can see, there are three valid user accounts - Scott, Jisun, and Sam - and all three have the same password (password). The code loops through the users and passwords arrays looking for a valid username and password match. If both the username and password are valid, we need to login the user and then redirect them to the appropriate page. If the credentials are invalid, then we display the InvalidCredentialsMessage Label.

When a user enters valid credentials, I mentioned that they are then redirected to the appropriate page. What is the appropriate page, though? Recall that when a user visits a page they are not authorized to view, the FormsAuthenticationModule automatically redirects them to the login page. In doing so, it includes the requested URL in the querystring via the ReturnUrl parameter. That is, if a user attempted to visit ProtectedPage.aspx, and they were not authorized to do so, the FormsAuthenticationModule would redirect them to:

Login.aspx?ReturnUrl=ProtectedPage.aspx

Upon successfully logging in, the user should be redirected back to ProtectedPage.aspx. Alternatively, users may visit the login page on their own volition. In that case, after logging in the user they should be sent to the root folder's Default.aspx page.

Logging In the User

Assuming that the supplied credentials are valid, we need to create a forms authentication ticket, thereby

logging in the user to the site. The FormsAuthentication class in the System.Web.Security namespace provides assorted methods for logging in and logging out users via the forms authentication system. While there are several methods in the FormsAuthentication class, the three we are interested in at this juncture are:

- GetAuthCookie(*username*, *persistCookie*) - creates a forms authentication ticket for the supplied name *username*. Next, this method creates and returns an HttpCookie object that holds the contents of the authentication ticket. If *persistCookie* is True, a persistent cookie is created.
- SetAuthCookie(*username*, *persistCookie*) - calls the GetAuthCookie(*username*, *persistCookie*) method to generate the forms authentication cookie. This method then adds the cookie returned by GetAuthCookie to the Cookies collection (assuming cookies-based forms authentication is being used; otherwise, this method calls an internal class that handles the cookieless ticket logic).
- RedirectFromLoginPage(*username*, *persistCookie*) - this method calls SetAuthCookie(*username*, *persistCookie*), and then redirects the user to the appropriate page.

GetAuthCookie is handy when you need to modify the authentication ticket before writing the cookie out to the Cookies collection. SetAuthCookie is useful if you want to create the forms authentication ticket and add it to the Cookies collection, but do not want to redirect the user to the appropriate page. Perhaps you want to keep them on the login page or send them to some alternate page.

Since we want to log in the user and redirect them to the appropriate page, let's use RedirectFromLoginPage. Update the LoginButton's Click event handler, replacing the two commented TODO lines with the following line of code:

```
FormsAuthentication.RedirectFromLoginPage(UserName.Text, RememberMe.Checked)
```

When creating the forms authentication ticket we use the UserName TextBox's Text property for the forms authentication ticket *username* parameter, and the checked state of the RememberMe CheckBox for the *persistCookie* parameter.

To test the login page, visit it in a browser. Start by entering invalid credentials, such as a username of Nope and a password of wrong. Upon clicking the Login button a postback will occur and the InvalidCredentialsMessage Label will be displayed.

Figure 10: The InvalidCredentialsMessage Label is Displayed When Entering Invalid Credentials(Click to view full-size image)

Next, enter valid credentials and click the Login button. This time when the postback occurs a forms authentication ticket is created and you are automatically redirected back to Default.aspx. At this point you have logged in to the website, although there are no visual cues to indicate that you are currently logged in. In Step 4

we will see how to programmatically determine whether a user is logged in or not as well as how to identify the user visiting the page.

Step 5 examines techniques for logging a user out of the website.

Securing the Login Page

When the user enters her credentials and submits the login page form, the credentials - including her password - are transmitted over the Internet to the web server in *plain text*. That means any hacker sniffing the network traffic can see the username and password. To prevent this, it is essential to encrypt the network traffic by using Secure Socket Layers (SSL). This will ensure that the credentials (as well as the entire page's HTML markup) are encrypted from the moment they leave the browser until they are received by the web server.

Unless your website contains sensitive information, you will only need to use SSL on the login page and on other pages where the user's password would otherwise be sent over the wire in plain text. You do not need to worry about securing the forms authentication ticket since, by default, it is both encrypted and digitally signed (to prevent tampering). A more thorough discussion on forms authentication ticket security is presented in the following tutorial.

> **NOTE**
>
> Many financial and medical websites are configured to use SSL on *all* pages accessible to authenticated users. If you are building such a website you can configure the forms authentication system so that the forms authentication ticket is only transmitted over a secure connection. We will look at the various forms authentication configuration options in the next tutorial, *Forms Authentication Configuration and Advanced Topics*.

Step 4: Detecting Authenticated Visitors and Determining Their Identity

At this point we have enabled forms authentication and created a rudimentary login page, but we have yet to examine how we can determine whether a user is authenticated or anonymous. In certain scenarios we may wish to display different data or information depending on whether an authenticated or anonymous user is visiting the page. Moreover, we oftentimes need to know the identity of the authenticated user.

Let's augment the existing Default.aspx page to illustrate these techniques. In Default.aspx add two Panel controls, one named AuthenticatedMessagePanel and another named AnonymousMessagePanel. Add a Label control named WelcomeBackMessage in the first Panel. In the second Panel add a HyperLink control, set its Text property to Log In and its NavigateUrl property to ~/Login.aspx. At this point the declarative markup for Default.aspx should look similar to the following:

```
<%@ Page Language="VB" MasterPageFile="~/Site.master" AutoEventWireup="false" CodeFile="Default.aspx.vb"
Inherits="_Default" Title="Untitled Page" %>
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
 <asp:Panel runat="server" ID="AuthenticatedMessagePanel">
 <asp:Label runat="server" ID="WelcomeBackMessage"></asp:Label>
 </asp:Panel>
 <asp:Panel runat="Server" ID="AnonymousMessagePanel">
 <asp:HyperLink runat="server" ID="lnkLogin" Text="Log In" NavigateUrl="~/Login.aspx"></asp:HyperLink>
 </asp:Panel>
</asp:Content>
```

As you have probably guessed by now, the idea here is to display just the AuthenticatedMessagePanel to authenticated visitors and just the AnonymousMessagePanel to anonymous visitors. To accomplish this we need to set these Panels' Visible properties depending on whether the user is logged in or not.

The Request.IsAuthenticated property returns a Boolean value indicating whether the request has been

authenticated. Enter the following code into the Page_Load event handler code:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Request.IsAuthenticated Then
 WelcomeBackMessage.Text = "Welcome back!"
 AuthenticatedMessagePanel.Visible = True
 AnonymousMessagePanel.Visible = False
 Else
 AuthenticatedMessagePanel.Visible = False
 AnonymousMessagePanel.Visible = True
 End If
End Sub
```

With this code in place, visit Default.aspx through a browser. Assuming that you have yet to log in, you will see a link to the login page (see Figure 11). Click this link and log in to the site. As we saw in Step 3, after entering your credentials you will be returned to Default.aspx, but this time the page shows the Welcome back! message (see Figure 12).

Figure 11: When Visiting Anonymously, a Log In Link is Displayed(Click to view full-size image)

Figure 12: Authenticated Users are Shown the Welcome back! Message(Click to view full-size image)

We can determine the currently logged on user's identity via the HttpContext object's User property. The HttpContext object represents information about the current request, and is the home for such common ASP.NET objects as Response, Request, and Session, among others. The User property represents the security context of the current HTTP request and implements the IPrincipal interface.

The User property is set by the FormsAuthenticationModule. Specifically, when the FormsAuthenticationModule finds a forms authentication ticket in the incoming request, it creates a new GenericPrincipal object and assigns it to the User property.

Principal objects (like GenericPrincipal) provide information on the user's identity and the roles to which they belong. The IPrincipal interface defines two members:

- IsInRole(*roleName*) - a method that returns a Boolean value indicating if the principal belongs to the specified role.
- Identity - a property that returns an object that implements the IIdentity interface. The IIdentity interface defines three properties: AuthenticationType, IsAuthenticated, and Name.

We can determine the name of the current visitor using the following code:

```
Dim currentUsersName As String = User.Identity.Name
```

When using forms authentication, a FormsIdentity object is created for the GenericPrincipal's Identity property. The FormsIdentity class always returns the string Forms for its AuthenticationType property and True for its IsAuthenticated property. The Name property returns the username specified when creating the forms authentication ticket. In addition to these three properties, FormsIdentity includes access to the underlying authentication ticket via its Ticket property. The Ticket property returns an object of type FormsAuthenticationTicket, which has properties like Expiration, IsPersistent, IssueDate, Name, and so on.

The important point to take away here is that the *username* parameter specified in the FormsAuthentication.GetAuthCookie(*username*, *persistCookie*), FormsAuthentication.SetAuthCookie(*username*, *persistCookie*), and FormsAuthentication.RedirectFromLoginPage(*username*, *persistCookie*) methods is the same value returned by User.Identity.Name. Moreover, the authentication ticket created by these methods is available by casting User.Identity to a FormsIdentity object and then accessing the Ticket property:

```
Dim ident As FormsIdentity = CType(User.Identity, FormsIdentity)

Dim authTicket As FormsAuthenticationTicket = ident.Ticket
```

Let's provide a more personalized message in Default.aspx. Update the Page_Load event handler so that the WelcomeBackMessage Label's Text property is assigned the string Welcome back, *username*!

```
WelcomeBackMessage.Text = "Welcome back, " & User.Identity.Name & "!"
```

Figure 13 shows the effect of this modification (when logging in as user Scott).

Figure 13: The Welcome Message Includes the Currently Logged In User's Name(Click to view full-size image)

Using the LoginView and LoginName Controls

Displaying different content to authenticated and anonymous users is a common requirement; so is displaying the name of the currently logged on user. For that reason, ASP.NET includes two Web controls that provide the same functionality shown in Figure 13, but without the need to write a single line of code.

The LoginView control is a template-based Web control that makes it easy to display different data to authenticated and anonymous users. The LoginView includes two predefined templates:

- AnonymousTemplate - any markup added to this template is only displayed to anonymous visitors.
- LoggedInTemplate - this template's markup is shown only to authenticated users.

Let's add the LoginView control to our site's master page, Site.master. Rather than adding just the LoginView control, though, let's add both a new ContentPlaceHolder control and then put the LoginView control within that new ContentPlaceHolder. The rationale for this decision will become apparent shortly.

> **NOTE**
>
> In addition to the AnonymousTemplate and LoggedInTemplate, the LoginView control can include role-specific templates. Role-specific templates show markup only to those users that belong to a specified role. We will examine the role-based features of the LoginView control in a future tutorial.

Start by adding a ContentPlaceHolder named LoginContent into the master page within the navigation element. You can simply drag a ContentPlaceHolder control from the Toolbox onto the Source view, placing the resulting markup right above the TODO: Menu will go here text.

```
<div id="navigation">
 <asp:ContentPlaceHolder ID="LoginContent" runat="server">
 </asp:ContentPlaceHolder>
 TODO: Menu will go here...
</div>
```

Next, add a LoginView control within the LoginContent ContentPlaceHolder. Content placed into the master page's ContentPlaceHolder controls are considered *default content* for the ContentPlaceHolder. That is, ASP.NET pages that use this master page can specify their own content for each ContentPlaceHolder or use the master page's default content.

The LoginView and other login-related controls are located in the Toolbox's Login tab.

Figure 14: The LoginView Control in the Toolbox(Click to view full-size image)

Next, add two <br /> elements immediately after the LoginView control, but still within the ContentPlaceHolder. At this point, the navigation element's markup should look like the following:

```
<div id="navigation">
 <asp:ContentPlaceHolder ID="LoginContent" runat="server">
 <asp:LoginView ID="LoginView1" runat="server">
 </asp:LoginView>
 <br /><br />
 </asp:ContentPlaceHolder>
 TODO: Menu will go here...
</div>
```

The LoginView's templates can be defined from the Designer or the declarative markup. From Visual Studio's Designer, expand the LoginView's smart tag, which lists the configured templates in a drop-down list. Type in the text Hello, stranger into the AnonymousTemplate; next, add a HyperLink control and set its Text and NavigateUrl properties to Log In and ~/Login.aspx, respectively.

After configuring the AnonymousTemplate, switch to the LoggedInTemplate and enter the text, "Welcome back, ". Then drag a LoginName control from the Toolbox into the LoggedInTemplate, placing it immediately after the "Welcome back, " text. The LoginName control, as its name implies, displays the name of the currently logged in user. Internally, the LoginName control simply outputs the User.Identity.Name property

After making these additions to the LoginView's templates, the markup should look similar to the following:

```
<div id="navigation">
 <asp:ContentPlaceHolder ID="LoginContent" runat="server">
 <asp:LoginView ID="LoginView1" runat="server">
 <LoggedInTemplate>
 Welcome back, <asp:LoginName ID="LoginName1" runat="server" />.
 </LoggedInTemplate>
 <AnonymousTemplate>
 Hello, stranger. <asp:HyperLink ID="lnkLogin" runat="server" NavigateUrl="~/Login.aspx">Log
In</asp:HyperLink>
 </AnonymousTemplate>
 </asp:LoginView>
 <br /><br />
 </asp:ContentPlaceHolder>
 TODO: Menu will go here...
</div>
```

With this addition to the Site.master master page, each page in our website will display a different message depending on whether the user is authenticated. Figure 15 shows the Default.aspx page when visited through a browser by user Jisun. The Welcome back, Jisun message is repeated twice: once in the master page's navigation section on the left (via the LoginView control we just added) and once in the Default.aspx's content area (via Panel controls and programmatic logic).

Figure 15: The LoginView Control Displays Welcome back, Jisun. (Click to view full-size image)

Because we added the LoginView to the master page, it can appear in every page on our site. However, there may be web pages where we don't want to show this message. One such page is the login page, since a link to the login page seems out of place there. Since we placed the LoginView control in a ContentPlaceHolder in the master page, we can override this default markup in our content page. Open Login.aspx and go to the Designer. Since we have not explicitly defined a Content control in Login.aspx for the LoginContent ContentPlaceHolder in the master page, the login page will show the master page's default markup for this ContentPlaceHolder. You can see this through the Designer - the LoginContent ContentPlaceHolder shows the default markup (the LoginView control).

Figure 16: The Login Page Shows the Default Content for the Master Page's LoginContent ContentPlaceHolder(Click to view full-size image)

To override the default markup for the LoginContent ContentPlaceHolder, simply right-click on the region in the Designer and choose the Create Custom Content option from the context menu. (When using Visual Studio 2008 the ContentPlaceHolder includes a smart tag that, when selected, offers the same option.) This adds a new Content control to the page's markup and thereby allows us to define custom content for this page. You could add a custom message here, such as Please log in, but let's just leave this blank.

> **NOTE**
>
> In Visual Studio 2005, creating custom content creates an empty Content control in the ASP.NET page. In Visual Studio 2008, however, creating custom content copies the master page's default content into the newly created Content control. If you are using Visual Studio 2008, then, after creating the new Content control make sure to clear out the content copied over from the master page.

Figure 17 shows the Login.aspx page when visited from a browser after making this change. Note that there is no Hello, stranger or Welcome back, *username* message in the left navigation as there is when visiting Default.aspx.

Figure 17: The Login Page Hides the Default LoginContent ContentPlaceHolder's Markup(Click to view full-size image)

Step 5: Logging Out

In Step 3 we looked at building a login page to log a user in to the site, but we have yet to see how to log a user out. In addition to methods for logging a user in, the FormsAuthentication class also provides a SignOut method. The SignOut method simply destroys the forms authentication ticket, thereby logging the user out of the site.

Offering a log out link is such a common feature that ASP.NET includes a control specifically designed to log a user out. The LoginStatus control displays either a Login LinkButton or a Logout LinkButton, depending on the user's authentication status. A Login LinkButton is rendered for anonymous users, whereas a Logout LinkButton is displayed to authenticated users. The text for the Login and Logout LinkButtons can be configured via the LoginStatus's LoginText and LogoutText properties.

Clicking the Login LinkButton causes a postback, from which a redirect is issued to the login page. Clicking the Logout LinkButton causes the LoginStatus control to invoke the FormsAuthentication.SignOff method and then redirects the user to a page. The page the logged off user is redirected to depends on the LogoutAction property, which can be assigned to one of the three following values:

- Refresh - the default; redirects the user to the page they were just visiting. If the page they were just visiting does not allow anonymous users, then the FormsAuthenticationModule will automatically redirect the user to the login page.

You may be curious as to why a redirect is performed here. If the user wants to remain on the same page, why the need for the explicit redirect? The reason is because when the Logoff LinkButton is clicked, the user still has the forms authentication ticket in their cookies collection. Consequently, the postback request is an authenticated request. The LoginStatus control calls the SignOut method, but that happens after the FormsAuthenticationModule has authenticated the user. Therefore, an explicit redirect causes the browser to re-request the page. By the time the browser re-requests the page, the forms authentication ticket has been removed and therefore the incoming request is anonymous.

- Redirect - the user is redirected to the URL specified by the LoginStatus's LogoutPageUrl property.
- RedirectToLoginPage - the user is redirected to the login page.

Let's add a LoginStatus control to the master page and configure it to use the Redirect option to send the user to a page that displays a message confirming that they have been signed out. Start by creating a page in the root

directory named Logout.aspx. Don't forget to associate this page with the Site.master master page. Next, enter a message in the page's markup explaining to the user that they have been logged out.

Next, return to the Site.master master page and add a LoginStatus control beneath the LoginView in the LoginContent ContentPlaceHolder. Set the LoginStatus control's LogoutAction property to Redirect and its LogoutPageUrl property to ~/Logout.aspx .

```
<div id="navigation">
 <asp:ContentPlaceHolder ID="LoginContent" runat="server">
 <asp:LoginView ID="LoginView1" runat="server">
 <LoggedInTemplate>
 Welcome back, <asp:LoginName ID="LoginName1" runat="server" />.
 </LoggedInTemplate>
 <AnonymousTemplate>
 Hello, stranger. <asp:HyperLink ID="lnkLogin" runat="server" NavigateUrl="~/Login.aspx">Log
In</asp:HyperLink>
 </AnonymousTemplate>
 </asp:LoginView>
 <br />
 <asp:LoginStatus ID="LoginStatus1" runat="server" LogoutAction="Redirect" LogoutPageUrl="~/Logout.aspx" />
 <br /><br />
 </asp:ContentPlaceHolder>
 TODO: Menu will go here...
</div>
```

Since the LoginStatus is outside of the LoginView control, it will appear for both anonymous and authenticated users, but that's OK because the LoginStatus will correctly display a Login or Logout LinkButton. With the addition of the LoginStatus control, the Log In HyperLink in the AnonymousTemplate is superfluous, so remove it.

Figure 18 shows Default.aspx when Jisun visits. Note that the left column displays the message, Welcome back, Jisun along with a link to log out. Clicking the log out LinkButton causes a postback, signs Jisun out of the system, and then redirects her to Logout.aspx. As Figure 19 shows, by the time Jisun reaches Logout.aspx she has already been signed out and is therefore anonymous. Consequently, the left column shows the text Welcome, stranger and a link to the login page.

Figure 18: Default.aspx Shows Welcome Back, Jisun Along with a Logout LinkButton(Click to view full-size image)

Figure 19: Logout.aspx Shows Welcome, stranger Along with a Login LinkButton(Click to view full-size image)

> **NOTE**
>
> I encourage you to customize the Logout.aspx page to hide the master page's LoginContent ContentPlaceHolder (like we did for Login.aspx in Step 4). The reason is because the Login LinkButton rendered by the LoginStatus control (the one beneath Hello, stranger) sends the user to the login page passing the current URL in the ReturnUrl querystring parameter. In short, if a user who has logged out clicks this LoginStatus's Login LinkButton, and then logs in, they will be redirected back to Logout.aspx, which could easily confuse the user.

Summary

In this tutorial we started with an examination of the forms authentication workflow and then turned to implementing forms authentication in an ASP.NET application. Forms authentication is powered by the FormsAuthenticationModule, which has two responsibilities: identifying users based on their forms authentication ticket, and redirecting unauthorized users to the login page.

The .NET Framework's FormsAuthentication class includes methods for creating, inspecting, and removing forms authentication tickets. The Request.IsAuthenticated property and User object provide additional programmatic support for determining whether a request is authenticated and information about the user's identity. There are also the LoginView, LoginStatus, and LoginName Web controls, which give developers a quick, code-free way for performing many common login-related tasks. We will examine these and other login-related Web controls in greater detail in future tutorials.

This tutorial provided a cursory overview of forms authentication. We did not examine the assorted configuration options, look at how cookieless forms authentication tickets work, or explore how ASP.NET protects the contents of the forms authentication ticket. We will discuss these topics and more in the next tutorial.

Happy Programming!

Download Code or Download PDF

In this tutorial we will examine the various forms authentication settings and see how to modify them through the forms element. This will entail a detailed look at customizing the forms authentication ticket's timeout value, using a login page with a custom URL (like SignIn.aspx instead of Login.aspx), and cookieless forms authentication tickets.

Introduction

In the previous tutorial we looked at the steps necessary for implementing forms authentication in an ASP.NET application, from specifying configuration settings in Web.config to creating a log in page to displaying different content for authenticated and anonymous users. Recall that we configured the website to use forms authentication by setting the mode attribute of the <authentication> element to Forms. The <authentication> element may optionally include a <forms> child element, through which an assortment of forms authentication settings may be specified.

In this tutorial we will examine the various forms authentication settings and see how to modify them through the <forms> element. This will entail a detailed look at customizing the forms authentication ticket's timeout value, using a login page with a custom URL (like SignIn.aspx instead of Login.aspx), and cookieless forms authentication tickets. We will also examine the makeup of the forms authentication ticket more closely and see the precautions ASP.NET takes to ensure that the ticket's data is secure from inspection and tampering. Finally, we will look at how to store extra user data in the forms authentication ticket and how to model this data through a custom principal object.

Step 1: Examining the <forms> Configuration Settings

The forms authentication system in ASP.NET offers a number of configuration settings that can be customized on an application-by-application basis. This includes settings like: the lifetime of the forms authentication ticket; what sort of protection is applied to the ticket; under what conditions cookieless authentication tickets are used; the path to the login page; and other information. To modify the default values, add a <forms> element as a child of the <authentication> element, specifying those property values you want to customize as XML attributes like so:

```
<authentication mode="Forms">

 <forms

 propertyName1="value1"

 propertyName2="value2"

 ...

 propertyNameN="valueN"

 />

</authentication>
```

Table 1 summarizes the properties that can be customized through the <forms> element. Since Web.config is an XML file, the attribute names in the left column are case-sensitive.

ATTRIBUTE	DESCRIPTION
cookieless	This attribute specifies under what conditions the authentication ticket is stored in a cookie versus being embedded in the URL. Allowable values are: UseCookies; UseUri; AutoDetect; and UseDeviceProfile (the default). Step 2 examines this setting in more detail.
defaultUrl	Indicates the URL that users are redirected to after signing in from the login page if there is no RedirectUrl value specified in the querystring. The default value is default.aspx.
domain	When using cookie-based authentication tickets, this setting specifies the cookie s domain value. The default value is an empty string, which causes the browser to use the domain from which it was issued (such as www.yourdomain.com). In this case, the cookie will **not** be sent when making requests to subdomains, such as admin.yourdomain.com. If you want the cookie to be passed to all subdomains you need to customize the domain attribute setting it to yourdomain.com.
enableCrossAppRedirects	A Boolean value indicating whether authenticated users are remembered when redirected to URLs in other web applications on the same server. The default is false.
loginUrl	The URL of the login page. The default value is login.aspx.
name	When using cookie-based authentication tickets, the name of the cookie. The default is .ASPXAUTH.
path	When using cookie-based authentication tickets, this setting specifies the cookie s path attribute. The path attribute enables a developer to limit the scope of a cookie to a particular directory hierarchy. The default value is /, which informs the browser to send the authentication ticket cookie to any request made to the domain.

ATTRIBUTE	DESCRIPTION
protection	Indicates what techniques are used to protect the forms authentication ticket. The allowable values are: All (the default); Encryption; None; and Validation. These settings are discussed in detail in Step 3.
requireSSL	A Boolean value that indicates whether an SSL connection is required to transmit the authentication cookie. The default value is false.
slidingExpiration	A Boolean value that indicates whether the authentication cookie s timeout is reset each time the user visits the site during a single session. The default value is true. The authentication ticket timeout policy is discussed in more detail in the Specifying the Ticket s Timeout Value section.
timeout	Specifies the time, in minutes, after which the authentication ticket cookie expires. The default value is 30. The authentication ticket timeout policy is discussed in more detail in the Specifying the Ticket s Timeout Value section.

Table 1: A Summary of the <forms> Element's Attributes

In ASP.NET 2.0 and beyond, the default forms authentication values are hard-coded in the FormsAuthenticationConfiguration class in the .NET Framework. Any modifications must be applied on an application-by-application basis in the Web.config file. This differs from ASP.NET 1.x, where the default forms authentication values were stored in the machine.config file (and could therefore be modified via editing machine.config). While on the topic of ASP.NET 1.x, it is worthwhile to mention that a number of the forms authentication system settings have different default values in ASP.NET 2.0 and beyond than in ASP.NET 1.x. If you are migrating your application from an ASP.NET 1.x environment, it is important to be aware of these differences. Consult the <forms> element technical documentation for a list of the differences.

> **NOTE**
> Several forms authentication settings, such as the timeout, domain, and path, specify details for the resulting forms authentication ticket cookie. For more information on cookies, how they work, and their various properties, read this Cookies tutorial.

Specifying the Ticket's Timeout Value

The forms authentication ticket is a token that represents an identity. With cookie-based authentication tickets, this token is held in the form of a cookie and sent to the web server on each request. Possession of the token, in essence, declares, I am *username*, I have already logged in, and is used so that a user's identity can be remembered across page visits.

The forms authentication ticket not only includes the user's identity, but also contains information to help ensure the integrity and security of the token. After all, we don't want a nefarious user to be able to create a counterfeit token, or to modify a legit token in some underhanded way.

One such bit of information included in the ticket is an *expiry*, which is the date and time the ticket is no longer valid. Each time the FormsAuthenticationModule inspects an authentication ticket, it ensures that the ticket's expiry has not yet passed. If it has, it disregards the ticket and identifies the user as being anonymous. This safeguard helps protect against replay attacks. Without an expiry, if a hacker was able to get her hands on a user's valid authentication ticket - perhaps by gaining physical access to their computer and rooting through their cookies - they could send a request to the server with this stolen authentication ticket and gain entry.

While the expiry doesn't prevent this scenario, it does limit the window during which such an attack can succeed.

> **NOTE**
>
> Step 3 details additional techniques used by the forms authentication system to protect the authentication ticket.

When creating the authentication ticket, the forms authentication system determines its expiry by consulting the timeout setting. As noted in Table 1, the timeout setting defaults to 30 minutes, meaning that when the forms authentication ticket is created its expiry is set to a date and time 30 minutes in the future.

The expiry defines an absolute time in the future when the forms authentication ticket expires. But usually developers want to implement a sliding expiry, one that is reset every time the user revisits the site. This behavior is determined by the slidingExpiration settings. If set to true (the default), each time the FormsAuthenticationModule authenticates a user, it updates the ticket's expiry. If set to false, the expiry is not updated on each request, thereby causing the ticket to expire exactly timeout number of minutes past when the ticket was first created.

> **NOTE**
>
> The expiry stored in the authentication ticket is an absolute date and time value, like August 2, 2008 11:34 AM. Moreover, the date and time are relative to the web server's local time. This design decision can have some interesting side effects around Daylight Saving Time (DST), which is when clocks in the United States are moved ahead one hour (assuming the web server is hosted in a locale where Daylight Saving Time is observed). Consider what would happen for an ASP.NET website with a 30 minute expiry near the time that DST begins (which is at 2:00 AM). Imagine a visitor signs on to the site on March 11, 2008 at 1:55 AM. This would generate a forms authentication ticket that expires at March 11, 2008 at 2:25 AM (30 minutes in the future). However, once 2:00 AM rolls around, the clock jumps to 3:00 AM because of DST. When the user loads a new page six minutes after signing in (at 3:01 AM), the FormsAuthenticationModule notes that the ticket has expired and redirects the user to the login page. For a more thorough discussion on this and other authentication ticket timeout oddities, as well as workarounds, pick up a copy of Stefan Schackow's *Professional ASP.NET 2.0 Security, Membership, and Role Management* (ISBN: 978-0-7645-9698-8).

Figure 1 illustrates the workflow when slidingExpiration is set to false and timeout is set to 30. Note that the authentication ticket generated at login contains the expiration date, and this value is not updated on subsequent requests. If the FormsAuthenticationModule finds that the ticket has expired, it discards it and treats the request as anonymous.

Figure 01: A Graphical Representation of the Forms Authentication Ticket's Expiry When slidingExpiration is false (Click to view full-size image)

Figure 2 shows the workflow when slidingExpiration is set to true and timeout is set to 30. When an authenticated request is received (with a non-expired ticket) its expiry is updated to timeout number of minutes in the future.

Figure 02: A Graphical Representation of the Forms Authentication Ticket's When slidingExpiration is true (Click to view full-size image)

When using cookie-based authentication tickets (the default), this discussion becomes a little more confusing because cookies can also have their own expiries specified. A cookie's expiry (or lack thereof) instructs the browser when the cookie should be destroyed. If the cookie lacks an expiry, it is destroyed when the browser shuts down. If an expiry is present, however, the cookie remains stored on the user's computer until the date and time specified in the expiry has passed. When a cookie is destroyed by the browser, it is no longer sent to the web server. Therefore, the destruction of a cookie is analogous to the user logging out of the site.

> **NOTE**
>
> Of course, a user may proactively remove any cookies stored on their computer. In Internet Explorer 7, you would go to Tools, Options, and click the Delete button in the Browsing history section. From there, click the Delete cookies button.

The forms authentication system creates session-based or expiry-based cookies depending on the value passed in to the *persistCookie* parameter. Recall that the FormsAuthentication class's GetAuthCookie, SetAuthCookie, and RedirectFromLoginPage methods take in two input parameters: *username* and *persistCookie*. The login page we created in the preceding tutorial included a Remember me CheckBox, which determined whether a persistent cookie was created. Persistent cookies are expiry-based; non-persistent cookies are session-based.

The timeout and slidingExpiration concepts already discussed apply the same to both session- and expiry-based cookies. There is only one minor difference in execution: when using expiry-based cookies with slidingTimeout set to true, the cookie's expiry is only updated when more than half of the specified time has elapsed.

Let's update our website's authentication ticket timeout policies so that tickets timeout after one hour (60 minutes), using a sliding expiration. To effect this change, update the Web.config file, adding a <forms> element to the <authentication> element with the following markup:

```
<authentication mode="Forms">

 <forms

 slidingExpiration="true"

 timeout="60"

 />

</authentication>
```

Using an Login Page URL Other than Login.aspx

Since the FormsAuthenticationModule automatically redirects unauthorized users to the login page, it needs to know the login page's URL. This URL is specified by the loginUrl attribute in the <forms> element and defaults to login.aspx. If you are porting over an existing website, you may already have a login page with a different URL, one that has already been bookmarked and indexed by search engines. Rather than renaming your existing login page to login.aspx and breaking links and users' bookmarks, you can instead modify the loginUrl attribute to point to your login page.

For example, if your login page was named SignIn.aspx and was located in the Users directory, you could point the loginUrl configuration setting to ~/Users/SignIn.aspx like so:

```
<authentication mode="Forms">

 <forms

 loginUrl="~/Users/SignIn.aspx"

 />

</authentication>
```

Since our current application already has a login page named Login.aspx, there's no need to specify a custom value in the <forms> element.

Step 2: Using Cookieless Forms Authentication Tickets

By default the forms authentication system determines whether to store its authentication tickets in the cookies collection or embed them in the URL based on the user agent visiting the site. All mainstream desktop browsers like Internet Explorer, Firefox, Opera, and Safari, support cookies, but not all mobile devices do.

The cookie policy used by the forms authentication system depends on the cookieless setting in the <forms> element, which can be assigned one of four values:

- UseCookies - specifies that cookie-based authentication tickets will always be used.
- UseUri - indicates that cookie-based authentication tickets will never be used.
- AutoDetect - if the device profile does not support cookies, cookie-based authentication tickets are not used; if the device profile supports cookies, a probing mechanism is used to determine if cookies are enabled.
- UseDeviceProfile - the default; uses cookie-based authentication tickets only if the device profile supports cookies. No probing mechanism is used.

The AutoDetect and UseDeviceProfile settings rely on a *device profile* in ascertaining whether to use cookie-based or cookieless authentication tickets. ASP.NET maintains a database of various devices and their capabilities, such as whether they support cookies, what version of JavaScript they support, and so on. Each time a device requests a web page from a web server it sends along a *user-agent* HTTP header that identifies

the device type. ASP.NET automatically matches the supplied user-agent string with the corresponding profile specified in its database.

> **NOTE**
> This database of device capabilities is stored in a number of XML files that adhere to the Browser Definition File schema. The default device profile files are located in %WINDIR%\Microsoft.Net\Framework\v2.0.50727\CONFIG\Browsers. You can also add custom files to your application's App_Browsers folder. For more information, see How To: Detect Browser Types in ASP.NET Web Pages.

Because the default setting is UseDeviceProfile, cookieless forms authentication tickets will be used when the site is visited by a device whose profile reports that it does not support cookies.

Encoding the Authentication Ticket in the URL

Cookies are a natural medium for including information from the browser in each request to a particular website, which is why the default forms authentication settings use cookies if the visiting device supports them. If cookies are not supported, an alternate means for passing the authentication ticket from the client to the server must be employed. A common workaround used in cookieless environments is to encode the cookie data in the URL.

The best way to see how such information can be embedded within the URL is to force the site to use cookieless authentication tickets. This can be accomplished by setting the cookieless configuration setting to UseUri:

```
<authentication mode="Forms">

 <forms

 cookieless="UseUri"

 slidingExpiration="true"

 timeout="60"

 />

</authentication>
```

Once you have made this change, visit the site through a browser. When visiting as an anonymous user, the URLs will look exactly like they did before. For example, when visiting Default.aspx page my browser's address bar shows the following URL:

```
http://localhost:2448/ASPNET\_Security\_Tutorial\_03\_CS/default.aspx
```

However, upon logging in, the forms authentication ticket is embedded into the URL. For example, after visiting the login page and logging in as Sam, I am returned to the Default.aspx page, but the URL this time is:

```
http://localhost:2448/ASPNET\_Security\_Tutorial\_03\_CS/(F(jaIOIDTJxIr12xYS-VVgkqKCVAuIoW30Bu0diWi6flQC-
FyMaLXJfow\_Vd9GZkB2Cv-rfezq0gKadKX0YPZCkA2))/default.aspx
```

The forms authentication ticket has been embedded within the URL. The string (F(jaIOIDTJxIr12xYS-VVgkqKCVAuIoW30Bu0diWi6flQC-FyMaLXJfow_Vd9GZkB2Cv-rfezq0gKadKX0YPZCkA2) represents the hex-encoded authentication ticket information, and is the same data that is usually stored within a cookie.

In order for cookieless authentication tickets to work, the system must encode all URLs on the page to include the authentication ticket data, otherwise the authentication ticket will be lost when the user clicks on a link. Thankfully, this embedding logic is performed automatically. To demonstrate this functionality, open the Default.aspx page and add a HyperLink control, setting its Text and NavigateUrl properties to Test Link and SomePage.aspx, respectively. It doesn't matter that there really isn't a page in our project named SomePage.aspx.

Save the changes to Default.aspx and then visit it through a browser. Log on to the site so that the forms authentication ticket is embedded in the URL. Next, from Default.aspx, click the Test Link link. What happened? If no page named SomePage.aspx exists, then a 404 error occurred, but that's not what's important here. Instead, focus on the Address bar in your browser. Note that it includes the forms authentication ticket in the URL!

```
http://localhost:2448/ASPNET\_Security\_Tutorial\_03\_CS/(F(jaIOIDTJxIr12xYS-VVgkqKCVAuIoW30Bu0diWi6flQC-
FyMaLXJfow\_Vd9GZkB2Cv-rfezq0gKadKX0YPZCkA2))/SomePage.aspx
```

The URL SomePage.aspx in the link was automatically converted into a URL that included the authentication ticket - we didn't have to write a lick of code! The form authentication ticket will automatically be embedded in the URL for any hyperlinks that do not start with http:// or /. It doesn't matter if the hyperlink appears in a call to Response.Redirect, in a HyperLink control, or in an anchor HTML element (i.e., ...). As long as the URL isn't something like http://www.someserver.com/SomePage.aspx or /SomePage.aspx, the forms authentication ticket will be embedded for us.

> **NOTE**
>
> Cookieless forms authentication tickets adhere to the same timeout policies as cookie-based authentication tickets. However, cookieless authentication tickets are more prone to replay attacks since the authentication ticket is embedded directly in the URL. Imagine a user who visits a website, logs in, and then pastes the URL in an email to a colleague. If the colleague clicks on that link before the expiry is reached, they will be logged in as the user who sent the email!

Step 3: Securing the Authentication Ticket

The forms authentication ticket is transmitted over the wire either in a cookie or embedded directly within the URL. In addition to identity information, the authentication ticket can also include user data (as we will see in Step 4). Consequently, it is important that the ticket's data is encrypted from prying eyes and (even more importantly) that the forms authentication system can guarantee that the ticket was not tampered with.

To ensure the privacy of the ticket's data, the forms authentication system can encrypt the ticket data. Failure to encrypt the ticket data sends potentially sensitive information over the wire in plain-text.

To guarantee a ticket's authenticity, the forms authentication system must *validate* the ticket. Validation is the act of ensuring that a particular piece of data has not been modified, and is accomplished via a *message authentication code (MAC)*. In a nutshell, the MAC is a small piece of information that identifies the data that needs to be validated (in this case, the ticket). If the data represented by the MAC is modified, then the MAC and the data will not match up. Moreover, it is computationally hard for a hacker to both modify the data and generate his own MAC to correspond with the modified data.

When creating (or modifying) a ticket, the forms authentication system creates a MAC and attaches it to the ticket's data. When a subsequent request arrives, the forms authentication system compares the MAC and ticket data to validate the authenticity of the ticket data. Figure 3 illustrates this workflow graphically.

Figure 03: The Ticket's Authenticity is Ensured through a MAC (Click to view full-size image)

What security measures are applied to the authentication ticket depends on the protection setting in the <forms> element. The protection setting may be assigned to one of the following three values:

- All - the ticket is both encrypted and digitally signed (the default).
- Encryption - only encryption is applied - no MAC is generated.
- None - the ticket is neither encrypted nor digitally signed.
- Validation - a MAC is generated, but the ticket data is sent over the wire in plain-text.

Microsoft strongly recommends using the All setting.

Setting the Validation and Decryption Keys

The encryption and hashing algorithms used by the forms authentication system to encrypt and validate the authentication ticket are customizable through the <machineKey> element in Web.config. Table 2 outlines the <machineKey> element's attributes and their possible values.

ATTRIBUTE	DESCRIPTION
decryption	Indicates the algorithm used for encryption. This attribute can have one of the following four values: - Auto - the default; determines the algorithm based on the length of the decryptionKey attribute. - AES - uses the Advanced Encryption Standard (AES) algorithm. - DES - uses the Data Encryption Standard (DES) This algorithm is considered computationally weak and should not be used. - 3DES - uses the Triple DES algorithm, which works by applying the DES algorithm three times.

ATTRIBUTE	DESCRIPTION
decryptionKey	The secret key used by the encryption algorithm. This value must either be a hexadecimal string of the appropriate length (based on the value in decryption), AutoGenerate, or either value appended with,IsolateApps. Adding IsolateApps instructs ASP.NET to use a unique value for each application. The default is AutoGenerate,IsolateApps.
validation	Indicates the algorithm used for validation. This attribute can have one of the following four values: - AES - uses the Advanced Encryption Standard (AES) algorithm. - MD5 - uses the Message-Digest 5 (MD5) algorithm. - SHA1 - uses the SHA1 algorithm (the default). - 3DES - uses the Triple DES algorithm.
validationKey	The secret key used by the validation algorithm. This value must either be a hexadecimal string of the appropriate length (based on the value in validation), AutoGenerate, or either value appended with,IsolateApps. Adding IsolateApps instructs ASP.NET to use a unique value for each application. The default is AutoGenerate,IsolateApps.

Table 2: The <machineKey> Element Attributes

A thorough discussion of these encryption and validation options, and the pros and cons of the various algorithms, is beyond the scope of this tutorial. For an in-depth look at these issues, including guidance on what encryption and validation algorithms to use, what key lengths to use, and how best to generate these keys, refer to *Professional ASP.NET 2.0 Security, Membership, and Role Management*.

By default, the keys used for encryption and validation are generated automatically for each application, and these keys are stored in the Local Security Authority (LSA). In short, the default settings guarantee unique keys on a web server-by-web server and application-by-application basis. Consequently, this default behavior will not work for the two following scenarios:

- **Web Farms** - in a web farm scenario, a single web application is hosted on multiple web servers for purposes of scalability and redundancy. Each incoming request is dispatched to a server in the farm, meaning that over the lifetime of a user's session, different servers may be used to handle his various requests. Consequently, each server must use the same encryption and validation keys so that the forms authentication ticket created, encrypted, and validated on one server can be decrypted and validated on a different server in the farm.
- **Cross Application Ticket Sharing** - a single web server may host multiple ASP.NET applications. If you need for these different applications to share a single forms authentication ticket, it is imperative that their encryption and validation keys match up.

When working in a web farm setting or sharing authentication tickets across applications on the same server, you will need to configure the <machineKey> element in the affected applications so that their decryptionKey and validationKey values match up.

While neither of the above scenarios applies to our sample application, we can still specify explicit decryptionKey and validationKey values and define the algorithms to be used. Add a <machineKey> setting to the Web.config file:

```
<configuration>

 <system.web>

 ... Some markup was removed for brevity ...

 <machineKey

 decryption="AES"

 validation="SHA1"

 decryptionKey="1513F567EE75F7FB5AC0AC4D79E1D9F25430E3E2F1BCDD3370BCFC4EFC97A541"

 validationKey="32CBA563F26041EE5B5FE9581076C40618DCC1218F5F447634EDE8624508A129"

 />

 </system.web>

</configuration>
```

For more information check out How To: Configure MachineKey in ASP.NET 2.0.

> **NOTE**
>
> The decryptionKey and validationKey values were taken from Steve Gibson's Perfect Passwords web page, which generates 64 random hexadecimal characters on each page visit. To lessen the likelihood of these keys making their way into your production applications, you are encouraged to replace the above keys with randomly generated ones from the Perfect Passwords page.

Step 4: Storing Additional User Data in the Ticket

Many web applications display information about or base the page's display on the currently logged on user. For example, a web page might show the user's name and the date she last logged on in the upper corner of every page. The forms authentication ticket stores the currently logged on user's username, but when any other information is needed, the page must go to the user store - typically a database - to lookup the information not stored in the authentication ticket.

With a little bit of code we can store additional user information in the forms authentication ticket. Such data can be expressed through the FormsAuthenticationTicket class's UserData property. This is a useful place to put small amounts of information about the user that is commonly needed. The value specified in the UserData property is included as part of the authentication ticket cookie and, like the other ticket fields, is encrypted and validated based on the forms authentication system's configuration. By default, UserData is an empty string.

In order to store user data in the authentication ticket, we need to write a bit of code in the login page that grabs the user-specific information and stores it in the ticket. Since UserData is a property of type String, the data stored in it must be properly serialized as a string. For example, imagine that our user store included each user's date of birth and the name of their employer, and we wanted to store these two property values in the authentication ticket. We could serialize these values into a string by concatenating the user's date of birth's string with a pipe (|), followed by the employer name. For a user born on August 15, 1974 that works for Northwind Traders, we would assign the UserData property the string: 1974-08-15|Northwind Traders .

Whenever we need to access the data stored in the ticket, we can do so by grabbing the current request's FormsAuthenticationTicket and deserializing the UserData property. In the case of the date of birth and employer name example, we would split the UserData string into two substrings based on the delimiter (|).

Figure 04: Additional User Information Can Be Stored in the Authentication Ticket (Click to view full-size image)

Writing Information to UserData

Unfortunately, adding user-specific information to a forms authentication ticket is not as straightforward as one might expect. The UserData property of the FormsAuthenticationTicket class is read-only and can only be specified through the FormsAuthenticationTicket class constructor. When specifying the UserData property in the constructor, we also need to provide the ticket's other values: the username, the issue date, the expiration, and so on. When we created the login page in the preceding tutorial, this was all handled for us by the FormsAuthentication class. When adding UserData to the FormsAuthenticationTicket, we will need to write code to replicate much of the functionality already provided by the FormsAuthentication class.

Let's explore the necessary code for working with UserData by updating the Login.aspx page to record additional information about the user to the authentication ticket. Pretend that our user store contains information about the company the user works for and their title, and that we want to capture this information in the authentication ticket. Update the Login.aspx page's LoginButton Click event handler so that the code looks like the following:

```
Protected Sub LoginButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
LoginButton.Click

 ' Three valid username/password pairs: Scott/password, Jisun/password, and Sam/password.

 Dim users() As String = {"Scott", "Jisun", "Sam"}

 Dim passwords() As String = {"password", "password", "password"}

 Dim companyName() As String = {"Northwind Traders", "Adventure Works", "Contoso"}

 Dim titleAtCompany() As String = {"Janitor", "Scientist", "Mascot"}

 For i As Integer = 0 To users.Length - 1

 Dim validUsername As Boolean = (String.Compare(UserName.Text, users(i), True) = 0)

 Dim validPassword As Boolean = (String.Compare(Password.Text, passwords(i), False) = 0)

 If validUsername AndAlso validPassword Then

 ' Query the user store to get this user's User Data

 Dim userDataString As String = String.Concat(companyName(i), "|", titleAtCompany(i))

 ' Create the cookie that contains the forms authentication ticket

 Dim authCookie As HttpCookie = FormsAuthentication.GetAuthCookie(UserName.Text, RememberMe.Checked)

 ' Get the FormsAuthenticationTicket out of the encrypted cookie

 Dim ticket As FormsAuthenticationTicket = FormsAuthentication.Decrypt(authCookie.Value)

 ' Create a new FormsAuthenticationTicket that includes our custom User Data

 Dim newTicket As FormsAuthenticationTicket = New FormsAuthenticationTicket(ticket.Version, ticket.Name,
ticket.IssueDate, ticket.Expiration, ticket.IsPersistent, userDataString)

 ' Update the authCookie's Value to use the encrypted version of newTicket

 authCookie.Value = FormsAuthentication.Encrypt(newTicket)

 ' Manually add the authCookie to the Cookies collection

 Response.Cookies.Add(authCookie)

 ' Determine redirect URL and send user there

 Dim redirUrl As String = FormsAuthentication.GetRedirectUrl(UserName.Text, RememberMe.Checked)

 Response.Redirect(redirUrl)

 End If

 Next

 ' If we reach here, the user's credentials were invalid

 InvalidCredentialsMessage.Visible = True

End Sub
```

Let's step through this code one line at a time. The method starts by defining four string arrays: users, passwords, companyName, and titleAtCompany. These arrays hold the usernames, passwords, company names, and titles for the user accounts in the system, of which there are three: Scott, Jisun, and Sam. In a real

application, these values would be queried from the user store, not hard-coded in the page's source code.

In the previous tutorial, if the supplied credentials were valid we simply called FormsAuthentication.RedirectFromLoginPage(UserName.Text, RememberMe.Checked), which performed the following steps:

1. Created the forms authentication ticket
2. Wrote the ticket to the appropriate store. For cookies-based authentication tickets, the browser's cookies collection is used; for cookieless authentication tickets, the ticket data is serialized into the URL
3. Redirected the user to the appropriate page

These steps are replicated in the code above. First, the string we will eventually store in the UserData property is formed by combining the company name and the title, delimiting the two values with a pipe character (|).

Dim userDataString As String = String.Concat(companyName(i), "|", titleAtCompany(i))

Next, the FormsAuthentication.GetAuthCookie method is invoked, which creates the authentication ticket, encrypts and validates it according to the configuration settings, and places it in an HttpCookie object.

Dim authCookie As HttpCookie = FormsAuthentication.GetAuthCookie(UserName.Text, RememberMe.Checked)

In order to work with the FormAuthenticationTicket embedded within the cookie, we need to call the FormAuthentication class's Decrypt method, passing in the cookie value.

Dim ticket As FormsAuthenticationTicket = FormsAuthentication.Decrypt(authCookie.Value)

We then create a *new* FormsAuthenticationTicket instance based on the existing FormsAuthenticationTicket's values. However, this new ticket includes the user-specific information (userDataString).

Dim newTicket As FormsAuthenticationTicket = New FormsAuthenticationTicket(ticket.Version, ticket.Name, ticket.IssueDate, ticket.Expiration, ticket.IsPersistent, userDataString)

We then encrypt (and validate) the new FormsAuthenticationTicket instance by calling the Encrypt method, and put this encrypted (and validated) data back into authCookie.

authCookie.Value = FormsAuthentication.Encrypt(newTicket)

Finally, authCookie is added to the Response.Cookies collection and the GetRedirectUrl method is called to determine the appropriate page to send the user.

```
Response.Cookies.Add(authCookie)

Dim redirUrl As String = FormsAuthentication.GetRedirectUrl(UserName.Text, RememberMe.Checked)

Response.Redirect(redirUrl)
```

All of this code is needed because the UserData property is read-only and the FormsAuthentication class does not provide any methods for specifying UserData information in its GetAuthCookie, SetAuthCookie, or RedirectFromLoginPage methods.

> **NOTE**
> The code we just examined stores user-specific information in a cookies-based authentication ticket. The classes responsible for serializing the forms authentication ticket to the URL are internal to the .NET Framework. Long story short, you cannot store user data in a cookieless forms authentication ticket.

Accessing the UserData Information

At this point each user's company name and title is stored in the forms authentication ticket's UserData property

when they log in. This information can be accessed from the authentication ticket on any page without requiring a trip to the user store. To illustrate how this information can be retrieved from the UserData property, let's update Default.aspx so that its welcome message includes not only the user's name, but also the company they work for and their title.

Currently, Default.aspx contains an AuthenticatedMessagePanel Panel with a Label control named WelcomeBackMessage. This Panel is only displayed to authenticated users. Update the code in Default.aspx's Page_Load event handler so that it looks like the following:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load

 If Request.IsAuthenticated Then

 WelcomeBackMessage.Text = "Welcome back, " & User.Identity.Name & "!"

 ' Get User Data from FormsAuthenticationTicket and show it in WelcomeBackMessage

 Dim ident As FormsIdentity = CType(User.Identity, FormsIdentity)

 If ident IsNot Nothing Then

 Dim ticket As FormsAuthenticationTicket = ident.Ticket

 Dim userDataString As String = ticket.UserData

 ' Split on the |

 Dim userDataPieces() As String = userDataString.Split("|".ToCharArray())

 Dim companyName As String = userDataPieces(0)

 Dim titleAtCompany As String = userDataPieces(1)

 WelcomeBackMessage.Text &= String.Format(" You are the {0} of {1}.", titleAtCompany, companyName)

 End If

 AuthenticatedMessagePanel.Visible = True

 AnonymousMessagePanel.Visible = False

 Else

 AuthenticatedMessagePanel.Visible = False

 AnonymousMessagePanel.Visible = True

 End If

End Sub
```

If Request.IsAuthenticated is True, then the WelcomeBackMessage's Text property is first set to Welcome back, *username*. Then, the User.Identity property is cast to a FormsIdentity object so that we can access the underlying FormsAuthenticationTicket. Once we have the FormsAuthenticationTicket, we deserialize the UserData property into the company name and title. This is accomplished by splitting the string on the pipe character. The company name and title are then displayed in the WelcomeBackMessage Label.

Figure 5 shows a screenshot of this display in action. Logging in as Scott displays a welcome back message that includes Scott's company and title.

Figure 05: The Currently Logged On User's Company and Title are Displayed (Click to view full-size image)

> **NOTE**
>
> The authentication ticket's UserData property serves as a cache for the user store. Like any cache, it needs to be updated when the underlying data is modified. For example, if there is a web page from which users can update their profile, the fields cached in the UserData property must be refreshed to reflect the changes made by the user.

Step 5: Using a Custom Principal

On each incoming request the FormsAuthenticationModule attempts to authenticate the user. If a non-expired authentication ticket is present, the FormsAuthenticationModule assigns the HttpContext.User property to a new GenericPrincipal object. This GenericPrincipal object has an Identity of type FormsIdentity, which includes a reference to the forms authentication ticket. The GenericPrincipal class contains the bare minimum functionality needed by a class that implements IPrincipal - it just has an Identity property and an IsInRole method.

The principal object has two responsibilities: to indicate what roles the user belongs to and to provide identity information. This is accomplished through the IPrincipal interface's IsInRole(*roleName*) method and Identity property, respectively. The GenericPrincipal class allows for a string array of role names to be specified via its constructor; its IsInRole(*roleName*) method merely checks to see if the passed in *roleName* exists within the string array. When the FormsAuthenticationModule creates the GenericPrincipal, it passes in an empty string array to the GenericPrincipal's constructor. Consequently, any call to IsInRole will always return False.

The GenericPrincipal class meets the needs for most forms based authentication scenarios where roles are not used. For those situations where the default role handling is insufficient or when you need to associate a custom IIdentity object with the user, you can create a custom IPrincipal object during the authentication workflow and assign it to the HttpContext.User property.

> **NOTE**
>
> As we will see in future tutorials, when ASP.NET's Roles framework is enabled it creates a custom principal object of type RolePrincipal and overwrites the forms authentication-created GenericPrincipal object. It does this in order to customize the principal's IsInRole method to interface with the Roles framework's API.

Since we have not concerned ourselves with roles yet, the only reason we would have for creating a custom principal at this juncture would be to associate a custom IIdentity object to the principal. In Step 4 we looked at storing additional user information in the authentication ticket's UserData property, in particular the user's company name and their title. However, the UserData information is only accessible through the authentication ticket and only then as a serialized string, meaning that anytime we want to view the user information stored in the ticket we need to parse the UserData property.

We can improve the developer experience by creating a class that implements IIdentity and includes

CompanyName and Title properties. That way, a developer can access the currently logged on user's company name and title directly through the CompanyName and Title properties without needed to know how to parse the UserData property.

Creating the Custom Identity and Principal Classes

For this tutorial, let's create the custom principal and identity objects in the App_Code folder. Start by adding an App_Code folder to your project - right-click on the project name in Solution Explorer, select the Add ASP.NET Folder option, and choose App_Code. The App_Code folder is a special ASP.NET folder that holds class files specific to the website.

> **NOTE**
>
> The App_Code folder should only be used when managing your project through the Website Project Model. If you are using the Web Application Project Model, create a standard folder and add the classes to that. For example, you could add a new folder named Classes, and place your code there.

Next, add two new class files to the App_Code folder, one named CustomIdentity.vb and one named CustomPrincipal.vb.

Figure 06: Add the CustomIdentity and CustomPrincipal Classes to Your Project (Click to view full-size image)

The CustomIdentity class is responsible for implementing the IIdentity interface, which defines the AuthenticationType, IsAuthenticated, and Name properties. In addition to those required properties, we are interested in exposing the underlying forms authentication ticket as well as properties for the user's company name and title. Enter the following code into the CustomIdentity class.

```
Imports Microsoft.VisualBasic

Public Class CustomIdentity

 Implements System.Security.Principal.IIdentity

 Private _ticket As FormsAuthenticationTicket

 Public Sub New(ByVal ticket As FormsAuthenticationTicket)

 _ticket = ticket

 End Sub

 Public ReadOnly Property AuthenticationType() As String Implements
```

```
System.Security.Principal.IIdentity.AuthenticationType

 Get

 Return "Custom"

 End Get

 End Property

 Public ReadOnly Property IsAuthenticated() As Boolean Implements
System.Security.Principal.IIdentity.IsAuthenticated

 Get

 Return True

 End Get

 End Property

 Public ReadOnly Property Name() As String Implements System.Security.Principal.IIdentity.Name

 Get

 Return _ticket.Name

 End Get

 End Property

 Public ReadOnly Property Ticket() As FormsAuthenticationTicket

 Get

 Return _ticket

 End Get

 End Property

 Public ReadOnly Property CompanyName() As String

 Get

 Dim userDataPieces() As String = _ticket.UserData.Split("|".ToCharArray())

 Return userDataPieces(0)

 End Get

 End Property

 Public ReadOnly Property Title() As String

 Get

 Dim userDataPieces() As String = _ticket.UserData.Split("|".ToCharArray())

 Return userDataPieces(1)

 End Get

 End Property

End Class
```

Note that the class includes a FormsAuthenticationTicket member variable (_ticket) and that this ticket

information must be supplied through the constructor. This ticket data is used in returning the identity's Name; its UserData property is parsed to return the values for the CompanyName and Title properties.

Next, create the CustomPrincipal class. Since we are not concerned with roles at this juncture, the CustomPrincipal class's constructor accepts only a CustomIdentity object; its IsInRole method always returns False.

```
Imports Microsoft.VisualBasic

Public Class CustomPrincipal

 Implements System.Security.Principal.IPrincipal

 Private _identity As CustomIdentity

 Public Sub New(ByVal identity As CustomIdentity)

 _identity = identity

 End Sub

 Public ReadOnly Property Identity() As System.Security.Principal.IIdentity Implements
System.Security.Principal.IPrincipal.Identity

 Get

 Return _identity

 End Get

 End Property

 Public Function IsInRole(ByVal role As String) As Boolean Implements
System.Security.Principal.IPrincipal.IsInRole

 Return False

 End Function

End Class
```

Assigning a CustomPrincipal Object to the Incoming Request's Security Context

We now have a class that extends the default IIdentity specification to include CompanyName and Title properties, as well as a custom principal class that uses the custom identity. We are ready to step into the ASP.NET pipeline and assign our custom principal object to the incoming request's security context.

The ASP.NET pipeline takes an incoming request and processes it through a number of steps. At each step, a particular event is raised, making it possible for developers to tap into the ASP.NET pipeline and modify the request at certain points in its lifecycle. The FormsAuthenticationModule, for example, waits for ASP.NET to raise the AuthenticateRequest event, at which point it inspects the incoming request for an authentication ticket. If an authentication ticket is found, a GenericPrincipal object is created and assigned to the HttpContext.User property.

After the AuthenticateRequest event, the ASP.NET pipeline raises the PostAuthenticateRequest event, which is where we can replace the GenericPrincipal object created by the FormsAuthenticationModule with an instance of our CustomPrincipal object. Figure 7 depicts this workflow.

Figure 07: The GenericPrincipal is Replaced by a CustomPrincipal in the PostAuthenticationRequest Event (Click to view full-size image)

In order to execute code in response to an ASP.NET pipeline event, we can either create the appropriate event handler in Global.asax or create our own HTTP Module. For this tutorial let's create the event handler in Global.asax. Start by adding Global.asax to your website. Right-click on the project name in Solution Explorer and add an item of type Global Application Class named Global.asax.

Figure 08: Add a Global.asax File to Your Website (Click to view full-size image)

The default Global.asax template includes event handlers for a number of the ASP.NET pipeline events, including the Start, End and Error event, among others. Feel free to remove these event handlers, as we do not need them for this application. The event we are interested in is PostAuthenticateRequest. Update your Global.asax file so its markup looks similar to the following:

```
<%@ Application Language="VB" %>

<%@ Import Namespace="System.Security.Principal" %>

<%@ Import Namespace="System.Threading" %>

<script runat="server">

 Sub Application_OnPostAuthenticateRequest(ByVal sender As Object, ByVal e As EventArgs)

 ' Get a reference to the current User

 Dim usr As IPrincipal = HttpContext.Current.User

 ' If we are dealing with an authenticated forms authentication request

 If usr.Identity.IsAuthenticated AndAlso usr.Identity.AuthenticationType = "Forms" Then

 Dim fIdent As FormsIdentity = CType(usr.Identity, FormsIdentity)

 ' Create a CustomIdentity based on the FormsAuthenticationTicket

 Dim ci As New CustomIdentity(fIdent.Ticket)

 ' Create the CustomPrincipal

 Dim p As New CustomPrincipal(ci)

 ' Attach the CustomPrincipal to HttpContext.User and Thread.CurrentPrincipal

 HttpContext.Current.User = p

 Thread.CurrentPrincipal = p

 End If

 End Sub

</script>
```

The Application_OnPostAuthenticateRequest method executes each time the ASP.NET runtime raises the PostAuthenticateRequest event, which happens once on each incoming page request. The event handler starts by checking to see if the user is authenticated and was authenticated via forms authentication. If so, a new CustomIdentity object is created and passed the current request's authentication ticket in its constructor. Following that, a CustomPrincipal object is created and passed the just-created CustomIdentity object in its constructor. Finally, the current request's security context is assigned to the newly created CustomPrincipal object.

Note that the last step - associating the CustomPrincipal object with the request's security context - assigns the principal to two properties: HttpContext.User and Thread.CurrentPrincipal. These two assignments are necessary because of the way security contexts are handled in ASP.NET. The .NET Framework associates a security context with each running thread; this information is available as an IPrincipal object through the Thread object's CurrentPrincipal property. What is a confusing is that ASP.NET has its own security context information (HttpContext.User).

In certain scenarios, the Thread.CurrentPrincipal property is examined when determining the security context; in other scenarios, HttpContext.User is used. For example, there are security features in .NET that allow developers to declaratively state what users or roles can instantiate a class or invoke specific methods (see Adding Authorization Rules to Business and Data Layers Using PrincipalPermissionAttributes). Underneath the covers, these declarative techniques determine the security context via the Thread.CurrentPrincipal property.

In other scenarios, the HttpContext.User property is used. For example, in the previous tutorial we used this

property to display the currently logged on user's username. Clearly, then, it is imperative that the security context information in the Thread.CurrentPrincipal and HttpContext.User properties match up.

The ASP.NET runtime automatically syncs these property values for us. However, this synchronization occurs after the AuthenticateRequest event, but *before* the PostAuthenticateRequest event. Consequently, when adding a custom principal in the PostAuthenticateRequest event we need to be certain to manually assign the Thread.CurrentPrincipal or else Thread.CurrentPrincipal and HttpContext.User will be out of sync. See Context.User vs. Thread.CurrentPrincipal for a more detailed discussion on this issue.

Accessing the CompanyName and Title Properties

Whenever a request arrives and is dispatched to the ASP.NET engine, the Application_OnPostAuthenticateRequest event handler in Global.asax will fire. If the request has been successfully authenticated by the FormsAuthenticationModule, the event handler will create a new CustomPrincipal object with a CustomIdentity object based on the forms authentication ticket. With this logic in place, accessing information about the currently logged on user's company name and title is incredibly straightforward.

Return to the Page_Load event handler in Default.aspx, where in Step 4 we wrote code to retrieve the form authentication ticket and parse the UserData property in order to display the user's company name and title. With the CustomPrincipal and CustomIdentity objects in use now, there's no need to parse the values out of the ticket's UserData property. Instead, simply get a reference to the CustomIdentity object and use its CompanyName and Title properties:

```
Dim ident As CustomIdentity = CType(User.Identity, CustomIdentity)

If ident IsNot Nothing Then

 WelcomeBackMessage.Text &= String.Format(" You are the {0} of {1}.", ident.Title, ident.CompanyName)

End If
```

Summary

In this tutorial we examined how to customize the forms authentication system's settings via Web.config. We looked at how the authentication ticket's expiration is handled and how the encryption and validation safeguards are used to protect the ticket from inspection and modification. Finally, we discussed using the authentication ticket's UserData property to store additional user information in the ticket itself, and how to use custom principal and identity objects to expose this information in a more developer-friendly manner.

This tutorial concludes our examination of forms authentication in ASP.NET. The next tutorial starts our journey into the Membership framework.

Happy Programming!

Creating the Membership Schema in SQL Server (C#)

9/16/2020 • 27 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

This tutorial starts by examining techniques for adding the necessary schema to the database in order to use the SqlMembershipProvider. Following that, we will examine the key tables in the schema and discuss their purpose and importance. This tutorial ends with a look at how to tell an ASP.NET application which provider the Membership framework should use.

Introduction

The previous two tutorials examined using forms authentication to identify website visitors. The forms authentication framework makes it easy for developers to log a user into a website and to remember them across page visits through the use of authentication tickets. The `FormsAuthentication` class includes methods for generating the ticket and adding it to the visitor's cookies. The `FormsAuthenticationModule` examines all incoming requests and, for those with a valid authentication ticket, creates and associates a `GenericPrincipal` and a `FormsIdentity` object with the current request. Forms authentication is merely a mechanism for granting an authentication ticket to a visitor when logging in and, on subsequent requests, parsing that ticket to determine the user's identity. For a web application to support user accounts, we still need to implement a user store and add functionality to validate credentials, register new users, and the myriad of other user account-related tasks.

Prior to ASP.NET 2.0, developers were on the hook for implementing all of these user account-related tasks. Fortunately the ASP.NET team recognized this shortcoming and introduced the Membership framework with ASP.NET 2.0. The Membership framework is a set of classes in the .NET Framework that provide a programmatic interface for accomplishing core user account-related tasks. This framework is built atop the provider model, which allows developers to plug a customized implementation into a standardized API.

As discussed in the *Security Basics and ASP.NET Support* tutorial, the .NET Framework ships with two built-in Membership providers: `ActiveDirectoryMembershipProvider` and `SqlMembershipProvider`. As its name implies, the `SqlMembershipProvider` uses a Microsoft SQL Server database as the user store. In order to use this provider in an application, we need to tell the provider what database to use as the store. As you might imagine, the `SqlMembershipProvider` expects the user store database to have certain database tables, views, and stored procedures. We need to add this expected schema to the selected database.

This tutorial starts by examining techniques for adding the necessary schema to the database in order to use the `SqlMembershipProvider`. Following that, we will examine the key tables in the schema and discuss their purpose and importance. This tutorial ends with a look at how to tell an ASP.NET application which provider the Membership framework should use.

Let's get started!

Step 1: Deciding Where to Place the User Store

An ASP.NET application's data is commonly stored in a number of tables in a database. When implementing the `SqlMembershipProvider` database schema we must decide whether to place the Membership schema in the same database as the application data or in an alternate database.

I recommend locating the Membership schema in the same database as the application data for the following reasons:

- **Maintainability** ' an application whose data is encapsulated in one database is easier to understand, maintain, and deploy than an application that has two separate databases.
- **Relational Integrity** ' by locating the Membership-related tables in the same database as the application tables it is possible to establish foreign key constraints between the primary keys in the Membership-related tables and related application tables.

Decoupling the user store and application data into separate databases only makes sense if you have multiple applications that each use separate databases, but need to share a common user store.

Creating a Database

The application we have been building since the second tutorial has not yet needed a database. We need one now, however, for the user store. Let's create one and then add to it the schema required by the `SqlMembershipProvider` provider (see Step 2).

> **NOTE**
>
> Throughout this tutorial series we will be using a Microsoft SQL Server 2005 Express Edition database to store our application tables and the `SqlMembershipProvider` schema. This decision was made for two reasons: first, due to its cost - free - the Express Edition is the most readably accessible version of SQL Server 2005; second, SQL Server 2005 Express Edition databases can be placed directly in the web application's `App_Data` folder, making it a cinch to package the database and web application together in one ZIP file and to redeploy it without any special setup instructions or configuration options. If you'd prefer to follow along using a non-Express Edition version of SQL Server, feel free. The steps are virtually identical. The `SqlMembershipProvider` schema will work with any version of Microsoft SQL Server 2000 and up.

From the Solution Explorer, right-click on the `App_Data` folder and choose to Add New Item. (If you do not see an `App_Data` folder in your project, right-click on the project in Solution Explorer, select Add ASP.NET Folder, and pick `App_Data`.) From the Add New Item dialog box, choose to add a new SQL Database named `SecurityTutorials.mdf`. In this tutorial we will add the `SqlMembershipProvider` schema to this database; in subsequent tutorials we will create additional tables to capture our application data.

Figure 1: Add a New SQL Database Named `SecurityTutorials.mdf` Database to the `App_Data` Folder (Click to view full-size image)

Adding a database to the `App_Data` folder automatically includes it in the Database Explorer view. (In the non-

Express Edition version of Visual Studio, the Database Explorer is called the Server Explorer.) Go to the Database Explorer and expand the just-added `SecurityTutorials` database. If you do not see the Database Explorer on screen, go to the View menu and choose Database Explorer, or hit Ctrl+Alt+S. As Figure 2 shows, the `SecurityTutorials` database is empty - it contains no tables, no views, and no stored procedures.

Figure 2: The `SecurityTutorials` Database is Currently Empty (Click to view full-size image)

Step 2: Adding the `SqlMembershipProvider` Schema to the Database

The `SqlMembershipProvider` requires a particular set of tables, views, and stored procedures to be installed in the user store database. These requisite database objects can be added using the `aspnet_regsql.exe` tool. This file is located in the `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\` folder.

> **NOTE**
>
> The `aspnet_regsql.exe` tool offers both command line functionality and a graphical user interface. The graphical interface is more user friendly and is what we will examine in this tutorial. The command line interface is useful when the addition of the `SqlMembershipProvider` schema needs to be automated, such as in build scripts or automated testing scenarios.

The `aspnet_regsql.exe` tool is used to add or remove *ASP.NET application services* to a specified SQL Server database. The ASP.NET application services encompass the schemas for the `SqlMembershipProvider` and `SqlRoleProvider`, along with the schemas for the SQL-based providers for other ASP.NET 2.0 frameworks. We need to provide two bits of information to the `aspnet_regsql.exe` tool:

- Whether we want to add or remove application services, and
- The database from which to add or remove the application services schema

In prompting for the database to use, the `aspnet_regsql.exe` tool asks us to provide the name of the server the database resides on, the security credentials for connecting to the database, and the database name. If you are using the non-Express Edition of SQL Server, you should already know this information, as it is the same information you must provide through a connection string when working with the database through an ASP.NET web page. Determining the server and database name when using a SQL Server 2005 Express Edition database in the `App_Data` folder, however, is a bit more involved.

The following section examines a straightforward way for specifying the server and database name for a SQL Server 2005 Express Edition database in the `App_Data` folder. If you are not using SQL Server 2005 Express Edition feel free to skip ahead to the Installing the Application Services section.

Determining the Server and Database Name for a SQL Server 2005 Express Edition Database in the `App_Data` Folder

In order to use the `aspnet_regsql.exe` tool we need to know the server and database names. The server name is `localhost\InstanceName`. Most likely, the *InstanceName* is `SQLExpress`. However, if you installed SQL Server

2005 Express Edition manually (that is, you did not install it automatically while installing Visual Studio), then it is possible that you selected a different instance name.

The database name is a bit trickier to determine. Databases in the `App_Data` folder typically have a database name that includes a globally unique identifier along with the path to the database file. We need to determine this database name in order to add the application services schema through `aspnet_regsql.exe`.

The easiest way to ascertain the database name is to examine it through SQL Server Management Studio. SQL Server Management Studio provides a graphical interface for managing SQL Server 2005 databases, but it does not ship with the Express Edition of SQL Server 2005. The good news is that you can download the free Express Edition of SQL Server Management Studio.

> **NOTE**
>
> If you also have a non-Express Edition version of SQL Server 2005 installed on your desktop then the full version of Management Studio is likely installed. You can use the full version to determine the database name, following the same steps as outlined below for the Express Edition.

Start by closing Visual Studio to ensure that any locks imposed by Visual Studio on the database file are closed. Next, launch SQL Server Management Studio and connect to the `localhost\InstanceName` database for SQL Server 2005 Express Edition. As noted earlier, chances are the instance name is `SQLExpress`. For the Authentication option, select Windows Authentication.

Figure 3: Connect to the SQL Server 2005 Express Edition Instance (Click to view full-size image)

After connecting to the SQL Server 2005 Express Edition instance, Management Studio displays folders for the Databases, the Security settings, the Server Objects, and so on. If you expand the Databases tab you will see that the `SecurityTutorials.mdf` database is *not* registered in the database instance - we need to attach the database first.

Right-click on the Databases folder and choose Attach from the context menu. This will display the Attach Databases dialog box. From here, click the Add button, browse to the `SecurityTutorials.mdf` database, and click OK. Figure 4 shows the Attach Databases dialog box after the `SecurityTutorials.mdf` database has been selected. Figure 5 shows Management Studio's Object Explorer after the database has been successfully attached.

Figure 4: Attach the `SecurityTutorials.mdf` Database (Click to view full-size image)

Figure 5: The `SecurityTutorials.mdf` Database Appears in the Databases Folder (Click to view full-size image)

As Figure 5 shows, the `SecurityTutorials.mdf` database has a rather abstruse name. Let's change it to a more memorable (and easier to type) name. Right-click on the database, choose Rename from the context menu, and rename it `SecurityTutorialsDatabase`. This does not change the filename, just the name the database uses to identify itself to SQL Server.

Figure 6: Rename the Database to `SecurityTutorialsDatabase` (Click to view full-size image)

At this point we know the server and database names for the `SecurityTutorials.mdf` database file: `localhost\InstanceName` and `SecurityTutorialsDatabase`, respectively. We are now ready to install the application services through the `aspnet_regsql.exe` tool.

Installing the Application Services

To launch the `aspnet_regsql.exe` tool, go to the start menu and choose Run. Enter `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\aspnet_regsql.exe` into the textbox and click OK. Alternatively, you can use Windows Explorer to drill down to the appropriate folder and double-click the `aspnet_regsql.exe` file. Either approach will net the same results.

Running the `aspnet_regsql.exe` tool without any command line arguments launches the ASP.NET SQL Server Setup Wizard graphical user interface. The wizard makes it easy to add or remove the ASP.NET application services on a specified database. The first screen of the wizard, shown in Figure 7, describes the purpose of the tool.

Figure 7: Use the ASP.NET SQL Server Setup Wizard Makes to Add the Membership Schema (Click to view full-size image)

The second step in the wizard asks us whether we want to add the application services or remove them. Since we want to add the tables, views, and stored procedures necessary for the `SqlMembershipProvider`, choose the Configure SQL Server for application services option. Later, if you want to remove this schema from your database, re-run this wizard, but instead choose the Remove application services information from an existing database option.

Figure 8: Choose the Configure SQL Server for Application Services Option (Click to view full-size image)

The third step prompts for the database information: the server name, authentication information, and the database name. If you have been following along with this tutorial and have added the `SecurityTutorials.mdf` database to `App_Data`, attached it to `localhost\InstanceName`, and renamed it to `SecurityTutorialsDatabase`, then use the following values:

- Server: `localhost\InstanceName`
- Windows authentication
- Database: `SecurityTutorialsDatabase`

Figure 9: Enter the Database Information (Click to view full-size image)

After entering the database information, click Next. The final step summarizes the steps that will be taken. Click Next to install the application services and then Finish to complete the wizard.

> **NOTE**
>
> If you used Management Studio to attach the database and rename the database file, be sure to detach the database and close Management Studio before reopening Visual Studio. To detach the `SecurityTutorialsDatabase` database, right-click on the database name and, from the Tasks menu, choose Detach.

Upon completion of the wizard, return to Visual Studio and navigate to the Database Explorer. Expand the Tables folder. You should see a series of tables whose names start with the prefix `aspnet_`. Likewise, a variety of views and stored procedures can be found under the Views and Stored Procedures folders. These database objects make up the application services schema. We will examine the membership- and role-specific database objects in Step 3.

Figure 10: A Variety of Tables, Views, and Stored Procedures Have Been Added to the Database (Click to view full-size image)

> **NOTE**
>
> The `aspnet_regsql.exe` tool's graphical user interface installs the entire application services schema. But when executing `aspnet_regsql.exe` from the command-line you can specify what particular application services components to install (or remove). Therefore, if you want to add just the tables, views, and stored procedures necessary for the `SqlMembershipProvider` and `SqlRoleProvider` providers, run `aspnet_regsql.exe` from the command-line. Alternatively, you can manually run the appropriate subset of T-SQL create scripts used by `aspnet_regsql.exe`. These scripts are located in the `WINDIR%\Microsoft.Net\Framework\v2.0.50727\` folder with names like `InstallCommon.sql`, `InstallMembership.sql`, `InstallRoles.sql`, `InstallProfile.sql`, `InstallSqlState.sql`, and so on.

At this point we have created the database objects needed by the `SqlMembershipProvider`. However, we still need to instruct the Membership framework that it should use the `SqlMembershipProvider` (versus, say, the `ActiveDirectoryMembershipProvider`) and that the `SqlMembershipProvider` should use the `SecurityTutorials` database. We'll look at how to specify what provider to use and how to customize the selected provider's

settings in Step 4. But first, let's take a deeper look at the database objects that were just created.

Step 3: A Look at the Schema's Core Tables

When working with the Membership and Roles frameworks in an ASP.NET application, the implementation details are encapsulated by the provider. In future tutorials we will interface with these frameworks via the .NET Framework's `Membership` and `Roles` classes. When using these high-level APIs we do not need to concern ourselves with the low-level details, like what queries are executed or what tables are modified by the `SqlMembershipProvider` and `SqlRoleProvider`.

Given this, we could confidently use the Membership and Roles frameworks without having explored the database schema created in Step 2. However, when creating the tables to store application data we may need to create entities that relate to users or roles. It helps to have a familiarity with the `SqlMembershipProvider` and `SqlRoleProvider` schemas when establishing foreign key constraints between the application data tables and those tables created in Step 2. Moreover, in certain rare circumstances we may need to interface with the user and role stores directly at the database level (instead of through the `Membership` or `Roles` classes).

Partitioning the User Store Into Applications

The Membership and Roles frameworks are designed such that a single user and role store can be shared among many different applications. An ASP.NET application that uses the Membership or Roles frameworks must specify what application partition to use. In short, multiple web applications can use the same user and role stores. Figure 11 depicts user and role stores that are partitioned into three applications: HRSite, CustomerSite, and SalesSite. These three web applications each have their own unique users and roles, yet they all physically store their user account and role information in the same database tables.

Figure 11: User Accounts May Be Partitioned Across Multiple Applications (Click to view full-size image)

The `aspnet_Applications` table is what defines these partitions. Each application that uses the database to store user account information is represented by a row in this table. The `aspnet_Applications` table has four columns: `ApplicationId`, `ApplicationName`, `LoweredApplicationName`, and `Description`. `ApplicationId` is of type `uniqueidentifier` and is the table's primary key; `ApplicationName` provides a unique human-friendly name for each application.

The other Membership- and Role-related tables link back to the `ApplicationId` field in `aspnet_Applications`. For example, the `aspnet_Users` table, which contains a record for each user account, has an `ApplicationId` foreign key field; ditto for the `aspnet_Roles` table. The `ApplicationId` field in these tables specifies the application

partition the user account or role belongs to.

Storing User Account Information

User account information is housed in two tables: `aspnet_Users` and `aspnet_Membership`. The `aspnet_Users` table contains fields that hold the essential user account information. The three most pertinent columns are:

- `UserId`
- `UserName`
- `ApplicationId`

`UserId` is the primary key (and of type `uniqueidentifier`). `UserName` is of type `nvarchar(256)` and, along with the password, makes up the user's credentials. (A user's password is stored in the `aspnet_Membership` table.) `ApplicationId` links the user account to a particular application in `aspnet_Applications`. There is a composite `UNIQUE` constraint on the `UserName` and `ApplicationId` columns. This ensures that in a given application each UserName is unique, yet it allows for the same `UserName` to be used in different applications.

The `aspnet_Membership` table includes additional user account information, like the user's password, email address, the last login date and time, and so forth. There is a one-to-one correspondence between records in the `aspnet_Users` and `aspnet_Membership` tables. This relationship is ensured by the `UserId` field in `aspnet_Membership`, which serves as the table's primary key. Like the `aspnet_Users` table, `aspnet_Membership` includes an `ApplicationId` field that ties this information to a particular application partition.

Securing Passwords

Password information is stored in the `aspnet_Membership` table. The `SqlMembershipProvider` allows for passwords to be stored in the database using one of the following three techniques:

- **Clear** - the password is stored in the database as plain-text. I strongly discourage using this option. If the database is compromised - be it by a hacker who finds a back door or a disgruntled employee who has database access - every single user's credentials are there for the taking.
- **Hashed** - passwords are hashed using a one-way hash algorithm and a randomly generated salt value. This hashed value (along with the salt) is stored in the database.
- **Encrypted** - an encrypted version of the password is stored in the database.

The password storage technique used depends on the `SqlMembershipProvider` settings specified in `Web.config`. We will look at customizing the `SqlMembershipProvider` settings in Step 4. The default behavior is to store the hash of the password.

The columns responsible for storing the password are `Password`, `PasswordFormat`, and `PasswordSalt`. `PasswordFormat` is a field of type `int` whose value indicates the technique used for storing the password: 0 for Clear; 1 for Hashed; 2 for Encrypted. `PasswordSalt` is assigned a randomly generated string regardless of the password storage technique used; the value of `PasswordSalt` is only used when computing the hash of the password. Finally, the `Password` column contains the actual password data, be it the plain-text password, the hash of the password, or the encrypted password.

Table 1 illustrates what these three columns might look like for the various storage techniques when storing the password MySecret! .

STORAGE TECHNIQUE<_O3A_P />	PASSWORD<_O3A_P />	PASSWORDFORMAT<_O3A_P />	PASSWORDSALT<_O3A_P />
Clear	MySecret!	0	tTnkPlesqissc2y2SMEygA==
Hashed	2oXm6sZHWbTHFgjgkGQsc2Ec9ZM=	1	wFgjUfhdUFOCKQiI61vtiQ==

STORAGE TECHNIQUE<_O3A_P />	PASSWORD<_O3A_P />	PASSWORDFORMAT<_O3A_P />	PASSWORDSALT<_O3A_P />
Encrypted	62RZgDvhxykkqsMchZ0Yly7HS6onhpaoCYaRxV8g0F4CW56OXUU3e7Inza9j9BKp	2	LSRzhGS/aa/oqAXGLHJNBw==

Table 1: Example Values for the Password-Related Fields When Storing the Password MySecret!

> **NOTE**
> The particular encryption or hashing algorithm used by the `SqlMembershipProvider` is determined by the settings in the `<machineKey>` element. We discussed this configuration element in Step 3 of the *Forms Authentication Configuration and Advanced Topics* tutorial.

Storing Roles and Role Associations

The Roles framework allows developers to define a set of roles and specify what users belong to what roles. This information is captured in the database through two tables: `aspnet_Roles` and `aspnet_UsersInRoles`. Each record in the `aspnet_Roles` table represents a role for a particular application. Much like the `aspnet_Users` table, the `aspnet_Roles` table has three columns pertinent to our discussion:

- `RoleId`
- `RoleName`
- `ApplicationId`

`RoleId` is the primary key (and of type `uniqueidentifier`). `RoleName` is of type `nvarchar(256)`. And `ApplicationId` links the user account to a particular application in `aspnet_Applications`. There is a composite `UNIQUE` constraint on the `RoleName` and `ApplicationId` columns, ensuring that in a given application each role name is unique.

The `aspnet_UsersInRoles` table serves as a mapping between users and roles. There are only two columns - `UserId` and `RoleId` - and together they make up a composite primary key.

Step 4: Specifying the Provider and Customizing Its Settings

All of the frameworks that support the provider model - such as the Membership and Roles frameworks - lack implementation details themselves and instead delegate that responsibility to a provider class. In the case of the Membership framework, the `Membership` class defines the API for managing user accounts, but it does not interact directly with any user store. Rather, the `Membership` class's methods hand off the request to the configured provider - we will be using the `SqlMembershipProvider`. When we invoke one of the methods in the `Membership` class, how does the Membership framework know to delegate the call to the `SqlMembershipProvider`?

The `Membership` class has a `Providers` property that contains a reference to all of the registered provider classes available for use by the Membership framework. Each registered provider has an associated name and type. The name offers a human-friendly way to reference a particular provider in the `Providers` collection, while the type identifies the provider class. Moreover, each registered provider may include configuration settings. Configuration settings for the Membership framework include `passwordFormat` and `requiresUniqueEmail`, among many others. See Table 2 for a complete list of configuration settings used by the `SqlMembershipProvider`.

The `Providers` property's contents are specified through the web application's configuration settings. By default, all web applications have a provider named `AspNetSqlMembershipProvider` of type `SqlMembershipProvider`. This default Membership provider is registered in `machine.config` (located at

`%WINDIR%\Microsoft.Net\Framework\v2.0.50727\CONFIG)`:

```
<membership>
 <providers>
 <add name="AspNetSqlMembershipProvider"
 type="System.Web.Security.SqlMembershipProvider, System.Web, Version=2.0.0.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a"
 connectionStringName="LocalSqlServer"
 enablePasswordRetrieval="false"
 enablePasswordReset="true"
 requiresQuestionAndAnswer="true"
 applicationName="/"
 requiresUniqueEmail="false"
 passwordFormat="Hashed"
 maxInvalidPasswordAttempts="5"
 minRequiredPasswordLength="7"
 minRequiredNonalphanumericCharacters="1"
 passwordAttemptWindow="10"
 passwordStrengthRegularExpression=""/>
 </providers>
</membership>
```

As the markup above shows, the `<membership>` element defines the configuration settings for the Membership framework while the `<providers>` child element specifies the registered providers. Providers may be added or removed using the `<add>` or `<remove>` elements; use the `<clear>` element to remove all currently registered providers. As the markup above shows, `machine.config` adds a provider named `AspNetSqlMembershipProvider` of type `SqlMembershipProvider`.

In addition to the `name` and `type` attributes, the `<add>` element contains attributes that define the values for various configuring settings. Table 2 lists the available `SqlMembershipProvider`-specific configuration settings, along with a description of each.

NOTE

Any default values noted in Table 2 refer to the default values defined in the `SqlMembershipProvider` class. Note that not all of the configuration settings in `AspNetSqlMembershipProvider` correspond to the default values of the `SqlMembershipProvider` class. For example, if not specified in a Membership provider, the `requiresUniqueEmail` setting defaults to true. However, the `AspNetSqlMembershipProvider` overrides this default value by explicitly specifying a value of `false`.

SETTING<_O3A_P />	DESCRIPTION<_O3A_P />
`ApplicationName`	Recall that the Membership framework allows for a single user store to be partitioned across multiple applications. This setting indicates the name of the application partition used by the Membership provider. If this value is not explicitly specified, it is set, at runtime, to the value of the application's virtual root path.
`commandTimeout`	Specifies the SQL command timeout value (in seconds). The default value is 30.
`connectionStringName`	The name of the connection string in the `<connectionStrings>` element to use to connect to the user store database. This value is required.

SETTING<_O3A_P />	DESCRIPTION<_O3A_P />
`description`	Provides a human-friendly description of the registered provider.
`enablePasswordRetrieval`	Specifies whether users may retrieve their forgotten password. The default value is `false`.
`enablePasswordReset`	Indicates whether users are allowed to reset their password. Defaults to `true`.
`maxInvalidPasswordAttempts`	The maximum number of unsuccessful login attempts that may occur for a given user during the specified `passwordAttemptWindow` before the user is locked out. The default value is 5.
`minRequiredNonalphanumericCharacters`	The minimum number of non-alphanumeric characters that must appear in a user's password. This value must be between 0 and 128; the default is 1.
`minRequiredPasswordLength`	The minimum number of characters required in a password. This value must be between 0 and 128; the default is 7.
`name`	The name of the registered provider. This value is required.
`passwordAttemptWindow`	The number of minutes during which failed login attempts are tracked. If a user supplies invalid login credentials `maxInvalidPasswordAttempts` times within this specified window, they are locked out. The default value is 10.
`PasswordFormat`	The password storage format: `Clear`, `Hashed`, or `Encrypted`. The default is `Hashed`.
`passwordStrengthRegularExpression`	If provided, this regular expression is used to evaluate the strength of the user's selected password when creating a new account or when changing their password. The default value is an empty string.
`requiresQuestionAndAnswer`	Specifies whether a user must answer his security question when retrieving or resetting his password. The default value is `true`.
`requiresUniqueEmail`	Indicates whether all user accounts in a given application partition must have a unique email address. The default value is `true`.
`type`	Specifies the type of the provider. This value is required.

Table 2: Membership and `SqlMembershipProvider` Configuration Settings

In addition to `AspNetSqlMembershipProvider`, other Membership providers may be registered on an application-by-application basis by adding similar markup to the `Web.config` file.

> **NOTE**
> The Roles framework works in much the same way: there is a default registered role provider in `machine.config` and the registered providers may be customized on an application-by-application basis in `Web.config`. We will examine the Roles framework and its configuration markup in detail in a future tutorial.

Customizing the `SqlMembershipProvider` Settings

The default `SqlMembershipProvider` (`AspNetSqlMembershipProvider`) has its `connectionStringName` attribute set to `LocalSqlServer`. Like the `AspNetSqlMembershipProvider` provider, the connection string name `LocalSqlServer` is defined in `machine.config`.

```
<connectionStrings>
 <add name="LocalSqlServer"
 connectionString="data source=.\SQLEXPRESS;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User Instance=true"
 providerName="System.Data.SqlClient"/>
</connectionStrings>
```

As you can see, this connection string defines a SQL 2005 Express Edition database located at |DataDirectory|aspnetdb.mdf'. The string |DataDirectory| is translated at runtime to point to the `~/App_Data/` directory, so the database path |DataDirectory|aspnetdb.mdf" translates to `~/App_Data` / `aspnet.mdf`.

If we did not specify any Membership provider information in our application's `Web.config` file, the application uses the default registered Membership provider, `AspNetSqlMembershipProvider`. If the `~/App_Data/aspnet.mdf` database does not exist, the ASP.NET runtime will automatically create it and add the application services schema. However, we don't want to use the `aspnet.mdf` database; rather, we want to use the `SecurityTutorials.mdf` database we created in Step 2. This modification can be accomplished in one of two ways:

- **Specify a value for the `LocalSqlServer` connection string name in `Web.config`.** By overwriting the `LocalSqlServer` connection string name value in `Web.config`, we can use the default registered Membership provider (`AspNetSqlMembershipProvider`) and have it correctly work with the `SecurityTutorials.mdf` database. This approach is fine if you are content with the configuration settings specified by `AspNetSqlMembershipProvider`. For more information on this technique, see Scott Guthrie's blog post, Configuring ASP.NET 2.0 Application Services to Use SQL Server 2000 or SQL Server 2005.
- **Add a new registered provider of type `SqlMembershipProvider` and configure its `connectionStringName` setting to point to the `SecurityTutorials.mdf` database.** This approach is useful in scenarios where you want to customize other configuration properties in addition to the database connection string. In my own projects I always use this approach because of its flexibility and readability.

Before we can add a new registered provider that references the `SecurityTutorials.mdf` database, we first need to add an appropriate connection string value in the `<connectionStrings>` section in `Web.config`. The following markup adds a new connection string named `SecurityTutorialsConnectionString` that references the SQL Server 2005 Express Edition `SecurityTutorials.mdf` database in the `App_Data` folder.

```
<configuration>
 <connectionStrings>
 <add name="SecurityTutorialsConnectionString"
 connectionString="Data
Source=.\SQLEXPRESS;AttachDbFilename=|DataDirectory|\SecurityTutorials.mdf;Integrated Security=True;User
Instance=True"
 providerName="System.Data.SqlClient"/>
 </connectionStrings>
 <system.web>
 ... Configuration markup  removed for brevity ...
 </system.web>
</configuration>
```

> **NOTE**
> If you are using an alternate database file, update the connection string as needed. For more information on forming the correct connection string, refer to ConnectionStrings.com.

Next, add the following Membership configuration markup to the `Web.config` file. This markup registers a new provider named `SecurityTutorialsSqlMembershipProvider`.

```
<configuration>
 <connectionStrings>
 <add name="SecurityTutorialsConnectionString"
 connectionString="Data
Source=.\SQLEXPRESS;AttachDbFilename=|DataDirectory|\SecurityTutorials.mdf;Integrated Security=True;User
Instance=True"
 providerName="System.Data.SqlClient"/>
 </connectionStrings>
 <system.web>
 <membership defaultProvider="SecurityTutorialsSqlMembershipProvider">
 <providers>
 <!--Add a customized SqlMembershipProvider -->
 <add name="SecurityTutorialsSqlMembershipProvider"
 type="System.Web.Security.SqlMembershipProvider"
 connectionStringName="SecurityTutorialsConnectionString"
 enablePasswordRetrieval="false"
 enablePasswordReset="true"
 requiresQuestionAndAnswer="true"
 applicationName="SecurityTutorials"
 requiresUniqueEmail="true"
 passwordFormat="Hashed"
 maxInvalidPasswordAttempts="5"
 minRequiredPasswordLength="7"
 minRequiredNonalphanumericCharacters="1"
 passwordAttemptWindow="10"
 passwordStrengthRegularExpression=""/>
 </providers>
 </membership>
 ... Configuration markup removed for brevity ...
 </system.web>
</configuration>
```

In addition to registering the `SecurityTutorialsSqlMembershipProvider` provider, the above markup defines the `SecurityTutorialsSqlMembershipProvider` as the default provider (via the `defaultProvider` attribute in the `<membership>` element). Recall that the Membership framework can have multiple registered providers. Since `AspNetSqlMembershipProvider` is registered as the first provider in `machine.config`, it serves as the default provider unless we indicate otherwise.

Currently, our application has two registered providers: `AspNetSqlMembershipProvider` and

`SecurityTutorialsSqlMembershipProvider`. However, before registering the `SecurityTutorialsSqlMembershipProvider` provider we could have cleared out all previously registered providers by adding a `<clear />` element immediately before our `<add>` element. This would clear out the `AspNetSqlMembershipProvider` from the list of registered providers, meaning that the `SecurityTutorialsSqlMembershipProvider` would be the only registered Membership provider. If we used this approach, then we would not need to mark the `SecurityTutorialsSqlMembershipProvider` as the default provider, since it would be the only registered Membership provider. For more information on using `<clear />`, see Using `<clear />` When Adding Providers.

Note that the `SecurityTutorialsSqlMembershipProvider`'s `connectionStringName` setting references the just-added `SecurityTutorialsConnectionString` connection string name, and that its `applicationName` setting has been set to a value of SecurityTutorials. Additionally, the `requiresUniqueEmail` setting has been set to `true`. All other configuration options are identical to the values in `AspNetSqlMembershipProvider`. Feel free to make any configuration modifications here, if you wish. For example, you could tighten the password strength by requiring two non-alphanumeric characters instead of one, or by increasing the password length to eight characters instead of seven.

> **NOTE**
>
> Recall that the Membership framework allows for a single user store to be partitioned across multiple applications. The Membership provider's `applicationName` setting indicates what application the provider uses when working with the user store. It is important that you explicitly set a value for the `applicationName` configuration setting because if the `applicationName` is not explicitly set, it is assigned to the web application's virtual root path at runtime. This works fine as long as the application's virtual root path doesn't change, but if you move the application to a different path, the `applicationName` setting will change too. When this happens, the Membership provider will start working with a different application partition than was previously used. User accounts created prior to the move will reside in a different application partition and those users will no longer be able to log into the site. For a more in-depth discussion on this matter, see Always Set the `applicationName` Property When Configuring ASP.NET 2.0 Membership and Other Providers.

Summary

At this point we have a database with the configured application services (`SecurityTutorials.mdf`) and have configured our web application so that the Membership framework uses the `SecurityTutorialsSqlMembershipProvider` provider we just registered. This registered provider is of type `SqlMembershipProvider` and has its `connectionStringName` set to the appropriate connection string (`SecurityTutorialsConnectionString`) and its `applicationName` value explicitly set.

We are now ready to use the Membership framework from our application. In the next tutorial we will examine how to create new user accounts. Following that we will explore authenticating users, performing user-based authorization, and storing additional user-related information in the database.

Happy Programming!

Download Code or Download PDF

In this tutorial we will explore using the Membership framework (via the SqlMembershipProvider) to create new user accounts. We will see how to create new users programmatically and through ASP.NET's built-in CreateUserWizard control.

Introduction

In the preceding tutorial we installed the application services schema in a database, which added the tables, views, and stored procedures needed by the `SqlMembershipProvider` and `SqlRoleProvider`. This created the infrastructure we will need for the remainder of the tutorials in this series. In this tutorial we will explore using the Membership framework (via the `SqlMembershipProvider`) to create new user accounts. We will see how to create new users programmatically and through ASP.NET's built-in CreateUserWizard control.

In addition to learning how to create new user accounts, we will also need to update the demo website we first created in the *An Overview of Forms Authentication* tutorial and then enhanced in the *Forms Authentication Configuration and Advanced Topics* tutorial. Our demo web application has a login page that validates users' credentials against hard-coded username/password pairs. Moreover, `Global.asax` includes code that creates custom `IPrincipal` and `IIdentity` objects for authenticated users. We will update the login page to validate users' credentials against the Membership framework and remove the custom principal and identity logic.

Let's get started!

The Forms Authentication and Membership Checklist

Before we begin working with the Membership framework, let's take a moment to review the important steps we have taken to reach this point. When using the Membership framework with the `SqlMembershipProvider` in a forms-based authentication scenario, the following steps need to be performed prior to implementing Membership functionality in your web application:

1. **Enable forms-based authentication.** As we discussed in *An Overview of Forms Authentication*, forms authentication is enabled by editing `Web.config` and setting the `<authentication>` element's `mode` attribute to `Forms`. With forms authentication enabled, each incoming request is examined for a *forms authentication ticket*, which, if present, identifies the requestor.
2. **Add the application services schema to the appropriate database.** When using the `SqlMembershipProvider` we need to install the application services schema to a database. Usually this schema is added to the same database that holds the application's data model. The *Creating the Membership Schema in SQL Server* tutorial looked at using the `aspnet_regsql.exe` tool to accomplish this.
3. **Customize the Web Application's Settings to reference the database from step 2.** The *Creating the Membership Schema in SQL Server* tutorial showed two ways to configure the web application so that the `SqlMembershipProvider` would use the database selected in step 2: by modifying the `LocalSqlServer` connection string name; or by adding a new registered provider to the list of Membership framework providers and customizing that new provider to use the database from step 2.

When building a web application that uses the `SqlMembershipProvider` and forms-based authentication, you will

need to perform these three steps before using the `Membership` class or the ASP.NET Login Web controls. Since we already performed these steps in previous tutorials, we are ready to start using the Membership framework!

Step 1: Adding New ASP.NET Pages

In this tutorial and the next three we will be examining various Membership-related functions and capabilities. We will need a series of ASP.NET pages to implement the topics examined throughout these tutorials. Let's create those pages and then a site map file `(Web.sitemap)`.

Start by creating a new folder in the project named `Membership`. Next, add five new ASP.NET pages to the `Membership` folder, linking each page with the `Site.master` master page. Name the pages:

- `CreatingUserAccounts.aspx`
- `UserBasedAuthorization.aspx`
- `EnhancedCreateUserWizard.aspx`
- `AdditionalUserInfo.aspx`
- `Guestbook.aspx`

At this point your project's Solution Explorer should look similar to the screen shot shown in Figure 1.

Figure 1: Five New Pages Have Been Added to the `Membership` Folder (Click to view full-size image)

Each page should, at this point, have the two Content controls, one for each of the master page's ContentPlaceHolders: `MainContent` and `LoginContent`.

```
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent"

Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="LoginContent"
Runat="Server">
</asp:Content>
```

Recall that the `LoginContent` ContentPlaceHolder's default markup displays a link to log on or log off the site, depending on whether the user is authenticated. The presence of the `Content2` Content control, however, overrides the master page's default markup. As we discussed in *An Overview of Forms Authentication* tutorial, this is useful in pages where we do not want to display login-related options in the left column.

For these five pages, however, we want to show the master page's default markup for the `LoginContent`

ContentPlaceHolder. Therefore, remove the declarative markup for the `Content2` Content control. After doing so, each of the five page's markup should contain just one Content control.

Step 2: Creating the Site Map

All but the most trivial websites need to implement some form of a navigational user interface. The navigation user interface may be a simple list of links to the various sections of the site. Alternatively, these links may be arranged into menus or tree views. As page developers, creating the navigational user interface is only half of the story. We also need some means to define the site's logical structure in a maintainable and updateable fashion. As new pages are added or existing pages removed, we want to be able to update a single source – the site map – and have those modifications reflected across the site's navigational user interface.

These two tasks – defining the site map and implementing a navigational user interface based on the site map – are easy to accomplish thanks to the Site Map framework and the Navigation Web controls added in ASP.NET version 2.0. The Site Map framework allows for a developer to define a site map and then to access it through a programmatic API (the `SiteMap` class). The built-in Navigation Web controls include a Menu control, the TreeView control, and the SiteMapPath control.

Like the Membership and Roles frameworks, the Site Map framework is built atop the provider model. The job of the Site Map provider class is to generate the in-memory structure used by the `SiteMap` class from a persistent data store, such as an XML file or a database table. The .NET Framework ships with a default Site Map provider that reads the site map data from an XML file (`XmlSiteMapProvider`), and this is the provider we will be using in this tutorial. For some alternate Site Map provider implementations, refer to the Further Readings section at the end of this tutorial.

The default Site Map provider expects a properly-formatted XML file named `Web.sitemap` to exist the root directory. Since we are using this default provider, we need to add such a file and define the site map's structure in the appropriate XML format. To add the file, right-click on the project name in Solution Explorer and choose Add New Item. From the dialog box, opt to add a file of type Site Map named `Web.sitemap`.

Figure 2: Add a File Named `Web.sitemap` to the Project's Root Directory (Click to view full-size image)

The XML site map file defines the website's structure as a hierarchy. This hierarchical relationship is modeled in the XML file via the ancestry of the `<siteMapNode>` elements. The `Web.sitemap` must start with a `<siteMap>` parent node that has precisely one `<siteMapNode>` child. This top-level `<siteMapNode>` element represents the root of the hierarchy, and may have an arbitrary number of descendent nodes. Each `<siteMapNode>` element must include a `title` attribute and may optionally include `url` and `description` attributes, among others; each non-empty `url` attribute must be unique.

Enter the following XML into the `Web.sitemap` file:

```
<?xml version="1.0" encoding="utf-8" ?>

<siteMap xmlns="http://schemas.microsoft.com/AspNet/SiteMap-File-1.0" >
     <siteMapNode url="~/Default.aspx" title="Home">
          <siteMapNode title="Membership">
               <siteMapNode url="~/Membership/CreatingUserAccounts.aspx" title="Creating User Accounts" />

               <siteMapNode url="~/Membership/UserBasedAuthorization.aspx" title="User-Based Authorization"
/>
               <siteMapNode url="~/Membership/Guestbook.aspx" title="Storing Additional User Information" />
          </siteMapNode>

     </siteMapNode>
</siteMap>
```

The above site map markup defines the hierarchy shown in Figure 3.

Figure 3: The Site Map Represents a Hierarchical Navigational Structure (Click to view full-size image)

Step 3: Updating the Master Page to Include a Navigational User Interface

ASP.NET includes a number of navigation-related Web controls for designing a user interface. These include the Menu, TreeView, and the SiteMapPath controls. The Menu and TreeView controls render the site map structure in a menu or a tree, respectively, whereas the SiteMapPath displays a breadcrumb that shows the current node being visited as well as its ancestors. The site map data can be bound to other data Web controls using the SiteMapDataSource and can be accessed programmatically via the `SiteMap` class.

Since a thorough discussion of the Site Map framework and the Navigation controls is beyond the scope of this tutorial series, rather than spend time crafting our own navigational user interface let's instead borrow the one used in my *Working with Data in ASP.NET 2.0* tutorial series, which uses a Repeater control to display a two-deep bulleted list of navigation links, as shown in Figure 4.

Adding a Two-Level List of Links in the Left Column

To create this interface, add the following declarative markup to the `Site.master` master page's left column where the text "TODO: Menu will go here..." currently resides.

```
<ul>
     <li>

          <asp:HyperLink runat="server" ID="lnkHome" NavigateUrl="~/Default.aspx">Home</asp:HyperLink>
     </li>
     <asp:Repeater runat="server" ID="menu" DataSourceID="SiteMapDataSource1">

          <ItemTemplate>
               <li>
                    <asp:HyperLink ID="lnkMenuItem" runat="server"
                         NavigateUrl='<%# Eval("Url") %>'><%# Eval("Title") %></asp:HyperLink>

                    <asp:Repeater ID="submenu" runat="server" DataSource="<%#
                         ((SiteMapNode) Container.DataItem).ChildNodes %>">
                         <HeaderTemplate>
                              <ul>
                         </HeaderTemplate>
                         <ItemTemplate>

                              <li>
                                   <asp:HyperLink ID="lnkMenuItem" runat="server" NavigateUrl='<%#
                                        Eval("Url") %>'><%# Eval("Title") %></asp:HyperLink>

                              </li>
                         </ItemTemplate>
                         <FooterTemplate>
                              </ul>
                         </FooterTemplate>
                    </asp:Repeater>
               </li>
          </ItemTemplate>
     </asp:Repeater>

</ul>

<asp:SiteMapDataSource ID="SiteMapDataSource1" runat="server" ShowStartingNode="false" />
```

The above markup binds a Repeater control named `menu` to a SiteMapDataSource, which returns the site map hierarchy defined in `Web.sitemap`. Since the SiteMapDataSource control's `ShowStartingNode` property is set to False it starts returning the site map's hierarchy starting with the descendents of the "Home" node. The Repeater displays each of these nodes (currently just "Membership") in an `<li>` element. Another, inner Repeater then displays the current node's children in a nested unordered list.

Figure 4 shows the above markup's rendered output with the site map structure we created in Step 2. The Repeater renders vanilla unordered list markup; the cascading style sheet rules defined in `Styles.css` are responsible for the aesthetically-pleasing layout. For a more detailed description of how the above markup works, refer to the Master Pages and Site Navigation tutorial.

Figure 4: The Navigational User Interface is Rendered Using Nested Unordered Lists (Click to view full-size image)

Adding Breadcrumb Navigation

In addition to the list of links in the left column, let's also have each page display a breadcrumb. A breadcrumb is a navigational user interface element that quickly shows users their current position within the site hierarchy. The SiteMapPath control uses the Site Map framework to determine the current page's location in the site map and then displays a breadcrumb based on this information.

Specifically, add a `<span>` element to the master page's header `<div>` element, and set the new `<span>` element's `class` attribute to "breadcrumb". (The `Styles.css` class contains a rule for a "breadcrumb" class.) Next, add a SiteMapPath to this new `<span>` element.

```
<div id="header">
     <span class="title">User Account Tutorials</span><br />
     <span class="breadcrumb">
          <asp:SiteMapPath ID="SiteMapPath1" runat="server">

          </asp:SiteMapPath>
     </span>
</div>
```

Figure 5 shows the output of the SiteMapPath when visiting `~/Membership/CreatingUserAccounts.aspx`.

Home > Membership > Creating User Accounts

Figure 5: The Breadcrumb Displays the Current Page and its Ancestors in the Site Map (Click to view full-size image)

Step 4: Removing the Custom Principal and Identity Logic

In the *Forms Authentication Configuration and Advanced Topics* tutorial we saw how to associate custom principal and identity objects to the authenticated user. We accomplished this by creating an event handler in `Global.asax` for the application's `PostAuthenticateRequest` event, which fires after the `FormsAuthenticationModule` has authenticated the user. In this event handler we replaced the `GenericPrincipal` and `FormsIdentity` objects added by the `FormsAuthenticationModule` with the `CustomPrincipal` and `CustomIdentity` objects we created in that tutorial.

While custom principal and identity objects are useful in certain scenarios, in most cases the `GenericPrincipal` and `FormsIdentity` objects are sufficient. Consequently, I think it would be worthwhile to return to the default behavior. Make this change by either removing or commenting out the `PostAuthenticateRequest` event handler or by deleting the `Global.asax` file entirely.

Step 5: Programmatically Creating a New User

To create a new user account through the Membership framework use the `Membership` class's `CreateUser` method. This method has input parameters for the username, password, and other user-related fields. On invocation, it delegates the creation of the new user account to the configured Membership provider and then returns a `MembershipUser` object representing the just-created user account.

The `CreateUser` method has four overloads, each accepting a different number of input parameters:

- `CreateUser(username, password)`
- `CreateUser(username, password, email)`
- `CreateUser(username, password, email, passwordQuestion, passwordAnswer, isApproved, MembershipCreateStatus)`
- `CreateUser(username, password, email, passwordQuestion, passwordAnswer, isApproved, providerUserKey, MembershipCreateStatus)`

These four overloads differ on the amount of information that is collected. The first overload, for example,

requires just the username and password for the new user account, whereas the second one also requires the user's email address.

These overloads exist because the information needed to create a new user account depends on the Membership provider's configuration settings. In the *Creating the Membership Schema in SQL Server* tutorial we examined specifying Membership provider configuration settings in `Web.config`. Table 2 included a complete list of the configuration settings.

One such Membership provider configuration setting that impacts what `CreateUser` overloads may be used is the `requiresQuestionAndAnswer` setting. If `requiresQuestionAndAnswer` is set to `true` (the default), then when creating a new user account we must specify a security question and answer. This information is later used if the user needs to reset or change their password. Specifically, at that time they are shown the security question and they must enter the correct answer in order to reset or change their password. Consequently, if the `requiresQuestionAndAnswer` is set to `true` then calling either of the first two `CreateUser` overloads results in an exception because the security question and answer are missing. Since our application is currently configured to require a security question and answer, we will need to use one of the latter two overloads when creating user's programmatically.

To illustrate using the `CreateUser` method, let's create a user interface where we prompt the user for their name, password, email, and an answer to a pre-defined security question. Open the `CreatingUserAccounts.aspx` page in the `Membership` folder and add the following Web controls to the Content control:

- A TextBox named `Username`
- A TextBox named `Password`, whose `TextMode` property is set to `Password`
- A TextBox named `Email`
- A Label named `SecurityQuestion` with its `Text` property cleared out
- A TextBox named `SecurityAnswer`
- A Button named `CreateAccountButton` whose Text property is set to "Create the User Account"
- A Label control named `CreateAccountResults` with its `Text` property cleared out

At this point your screen should look similar to the screen shot shown in Figure 6.

Figure 6: Add the Various Web Controls to the `CreatingUserAccounts.aspx` Page (Click to view full-size image)

The `SecurityQuestion` Label and `SecurityAnswer` TextBox are intended to display a pre-defined security question and collect the user's answer. Note that both the security question and answer are stored on a user-by-user

basis, so it is possible to allow each user to define their own security question. However, for this example I have decided to use a universal security question, namely: "What is your favorite color?"

To implement this pre-defined security question, add a constant to the page's code-behind class named `passwordQuestion`, assigning it the security question. Then, in the `Page_Load` event handler, assign this constant to the `SecurityQuestion` Label's `Text` property:

```
const string passwordQuestion = "What is your favorite color";

protected void Page_Load(object sender, EventArgs e)
{
     if (!Page.IsPostBack)
          SecurityQuestion.Text = passwordQuestion;
}
```

Next, create an event handler for the `CreateAccountButton`'s `Click` event and add the following code:

```
protected void CreateAccountButton_Click(object sender, EventArgs e)
{
     MembershipCreateStatus createStatus;
     MembershipUser newUser = Membership.CreateUser(Username.Text, Password.Text, Email.Text,
passwordQuestion, SecurityAnswer.Text, true, out createStatus);
     switch (createStatus)
     {
          case MembershipCreateStatus.Success:
               CreateAccountResults.Text = "The user account was successfully created!";
               break;
          case MembershipCreateStatus.DuplicateUserName:
               CreateAccountResults.Text = "There already exists a user with this username.";
               break;

          case MembershipCreateStatus.DuplicateEmail:
               CreateAccountResults.Text = "There already exists a user with this email address.";
               break;
          case MembershipCreateStatus.InvalidEmail:
               CreateAccountResults.Text = "There email address you provided in invalid.";
               break;
          case MembershipCreateStatus.InvalidAnswer:
               CreateAccountResults.Text = "There security answer was invalid.";
               break;
          case MembershipCreateStatus.InvalidPassword:
               CreateAccountResults.Text = "The password you provided is invalid. It must be seven
characters long and have at least one non-alphanumeric character.";

               break;
          default:
               CreateAccountResults.Text = "There was an unknown error; the user account was NOT created.";
               break;
     }
}
```

The `Click` event handler starts by defining a variable named `createStatus` of type `MembershipCreateStatus`. `MembershipCreateStatus` is an enumeration that indicates the status of the `CreateUser` operation. For example, if the user account is created successfully, the resulting `MembershipCreateStatus` instance will be set to a value of `Success`; on the other hand, if the operation fails because there already exists a user with the same username, it will be set to a value of `DuplicateUserName`. In the `CreateUser` overload we use, we need to pass a `MembershipCreateStatus` instance into the method as an `out` parameter. This parameter is set to the appropriate value within the `CreateUser` method, and we can examine its value after the method call to determine whether the user account was successfully created.

After calling `CreateUser`, passing in `createStatus`, a `switch` statement is used to output an appropriate

message depending on the value assigned to `createStatus`. Figures 7 shows the output when a new user has successfully been created. Figures 8 and 9 show the output when the user account is not created. In Figure 8, the visitor entered a five-letter password, which does not meet the password strength requirements spelled out in the Membership provider's configuration settings. In Figure 9, the visitor is attempting to create a user account with an existing username (the one created in Figure 7).

Figure 7: A New User Account is Successfully Created (Click to view full-size image)

Figure 8: The User Account is Not Created Because the Supplied Password is Too Weak (Click to view full-size image)

Figure 9: The User Account is Not Created Because the Username is Already in Use (Click to view full-size image)

> **NOTE**
>
> You may be wondering how to determine success or failure when using one of the first two `CreateUser` method overloads, neither of which has a parameter of type `MembershipCreateStatus`. These first two overloads throw a `MembershipCreateUserException` exception in the face of a failure, which includes a `StatusCode` property of type `MembershipCreateStatus`.

After creating a few user accounts, verify that the accounts have been created by listing the contents of the `aspnet_Users` and `aspnet_Membership` tables in the `SecurityTutorials.mdf` database. As Figure 10 shows, I have added two users via the `CreatingUserAccounts.aspx` page: Tito and Bruce.

Figure 10: There are Two Users in the Membership User Store: Tito and Bruce (Click to view full-size image)

While the Membership user store now includes Bruce and Tito's account information, we have yet to implement functionality that allows for Bruce or Tito to log on to the site. Currently, `Login.aspx` validates the user's credentials against a hard-coded set of username/password pairs – it does *not* validate the supplied credentials against the Membership framework. For now seeing the new user accounts in the `aspnet_Users` and `aspnet_Membership` tables will have to suffice. In the next tutorial, *Validating User Credentials Against the Membership User Store*, we will update the login page to validate against the Membership store.

> **NOTE**
> If you do not see any users in your `SecurityTutorials.mdf` database, it may be because your web application is using the default Membership provider, `AspNetSqlMembershipProvider`, which uses the `ASPNETDB.mdf` database as its user store. To determine if this is the problem, click the Refresh button in the Solution Explorer. If a database named `ASPNETDB.mdf` has been added to the `App_Data` folder, this is the problem. Return to Step 4 of the *Creating the Membership Schema in SQL Server* tutorial for instructions on how to properly configure the Membership provider.

In most create user account scenarios, the visitor is presented with some interface to enter their username, password, email, and other essential information, at which point a new account is created. In this step we looked at building such an interface by hand and then saw how to use the `Membership.CreateUser` method to programmatically add the new user account based on the user's inputs. Our code, however, just created the new user account. It did not perform any follow up actions, like logging in the user to the site under the just-created user account, or sending a confirmation email to the user. These additional steps would require additional code in the Button's `Click` event handler.

ASP.NET ships with the CreateUserWizard control, which is designed to handle the user account creation process, from rendering a user interface for creating new user accounts, to creating the account in the Membership framework and performing post-account creation tasks, such as sending a confirmation email and logging the just-created user into the site. Using the CreateUserWizard control is as simple as dragging the CreateUserWizard control from the Toolbox onto a page, and then setting a few properties. In most cases, you won't need to write a single line of code. We will explore this nifty control in detail in Step 6.

If new user accounts are only created through a typical Create Account web page, it is unlikely that you will ever need to write code that uses the `CreateUser` method, as the CreateUserWizard control will likely meet your needs. However, the `CreateUser` method is handy in scenarios where you need a highly customized Create Account user experience or when you need to programmatically create new user accounts through an alternative interface. For example, you might have a page that allows a user to upload an XML file that contains user information from some other application. The page might parses the contents of the uploaded XML file and create a new account for each user represented in the XML by calling the `CreateUser` method.

Step 6: Creating a New User with the CreateUserWizard Control

ASP.NET ships with a number of Login Web controls. These controls aid in many common user account- and login-related scenarios. The CreateUserWizard control is one such control that is designed to present a user interface for adding a new user account to the Membership framework.

Like many of the other Login-related Web controls, the CreateUserWizard can be used without writing a single line of code. It intuitively provides a user interface based on the Membership provider's configuration settings and internally calls the `Membership` class's `CreateUser` method after the user enters the necessary information and clicks the "Create User" button. The CreateUserWizard control is extremely customizable. There are a host of events that fire during various stages of the account creation process. We can create event handlers, as needed, to inject custom logic into the account creation workflow. Furthermore, the CreateUserWizard's appearance is very flexible. There are a number of properties that define the appearance of the default interface; if necessary, the control can be converted into a template or additional user registration "steps" may be added.

Let's start with a look at using the CreateUserWizard control's default interface and behavior. We'll then explore how to customize the appearance via the control's properties and events.

Examining the CreateUserWizard's Default Interface and Behavior

Return to the `CreatingUserAccounts.aspx` page in the `Membership` folder, switch to the Design or Split mode, and then add a CreateUserWizard control to the top of the page. The CreateUserWizard control is filed under the Toolbox's Login controls section. After adding the control, set its `ID` property to `RegisterUser`. As the screen

shot in Figure 11 shows, the CreateUserWizard renders an interface with textboxes for the new user's username, password, email address, and security question and answer.

Figure 11: The CreateUserWizard Control Renders a Generic Create User Interface (Click to view full-size image)

Let's take a moment to compare the default user interface generated by the CreateUserWizard control with the interface we created in Step 5. For starters, the CreateUserWizard control allows the visitor to specify both the security question and answer, whereas our manually-created interface used a pre-defined security question. The CreateUserWizard control's interface also includes validation controls, whereas we had yet to implement validation on our interface's form fields. And the CreateUserWizard control interface includes a "Confirm Password" textbox (along with a CompareValidator to ensure that the text entered the "Password" and "Compare Password" textboxes are equal).

What's interesting is that the CreateUserWizard control consults the Membership provider's configuration settings when rendering its user interface. For example, the security question and answer textboxes are only displayed if `requiresQuestionAndAnswer` is set to True. Likewise, CreateUserWizard automatically adds a RegularExpressionValidator control to ensure that the password strength requirements are met, and sets its `ErrorMessage` and `ValidationExpression` properties based on the `minRequiredPasswordLength`, `minRequiredNonalphanumericCharacters`, and `passwordStrengthRegularExpression` configuration settings.

The CreateUserWizard control, as its name implies, is derived from the Wizard control. Wizard controls are designed to provide an interface for completing multi-step tasks. A Wizard control may have an arbitrary number of `WizardSteps`, each of which is a template that defines the HTML and Web controls for that step. The Wizard control initially displays the first `WizardStep`, along with navigation controls that permit the user to proceed from one step to the next, or to return to previous steps.

As the declarative markup in Figure 11 shows, the CreateUserWizard control's default interface includes two `WizardSteps:`

- `CreateUserWizardStep` – renders the interface to collect information for creating the new user account. This is the step shown in Figure 11.
- `CompleteWizardStep` – renders a message indicating that the account has successfully been created.

The CreateUserWizard's appearance and behavior can be modified by converting either of these steps to templates, or by adding your own `WizardSteps`. We will look at adding a `WizardStep` to the registration interface in the *Storing Additional User Information* tutorial.

Let's see the CreateUserWizard control in action. Visit the `CreatingUserAccounts.aspx` page through a browser. Start by entering some invalid values into the CreateUserWizard's interface. Try entering a password that doesn't conform to the password strength requirements, or leaving the "User Name" textbox empty. The CreateUserWizard will display an appropriate error message. Figure 12 shows the output when attempting to create a user with an insufficiently strong password.

Figure 12: The CreateUserWizard Automatically Injects Validation Controls (Click to view full-size image)

Next, enter appropriate values into the CreateUserWizard and click the "Create User" button. Assuming the required fields have been entered and the password's strength is sufficient, the CreateUserWizard will create a new user account through the Membership framework and then display the `CompleteWizardStep`'s interface (see Figure 13). Behind the scenes, the CreateUserWizard calls the `Membership.CreateUser` method, just like we did in Step 5.

Figure 13: A New User Account has Successfully Been Created (Click to view full-size image)

> **NOTE**
>
> As Figure 13 shows, the `CompleteWizardStep`'s interface includes a Continue button. However, at this point clicking it just performs a postback, leaving the visitor on the same page. In the "Customizing the CreateUserWizard's Appearance and Behavior Through Its Properties" section we will look at how you can have this button send the visitor to `Default.aspx` (or some other page).

After creating a new user account, return to Visual Studio and examine the `aspnet_Users` and `aspnet_Membership`

tables like we did in Figure 10 to verify that the account was successfully created.

Customizing the CreateUserWizard's Behavior and Appearance Through Its Properties

The CreateUserWizard can be customized in a variety of ways, through properties, `WizardSteps`, and event handlers. In this section we will look at how to customize the control's appearance through its properties; the next section looks at extending the control's behavior through event handlers.

Virtually all of the text displayed in the CreateUserWizard control's default user interface can be customized through its plethora of properties. For example, the "User Name", "Password", "Confirm Password", "E-mail", "Security Question", and "Security Answer" labels displayed to the left of the textboxes can be customized by the `UserNameLabelText`, `PasswordLabelText`, `ConfirmPasswordLabelText`, `EmailLabelText`, `QuestionLabelText`, and `AnswerLabelText` properties, respectively. Likewise, there are properties for specifying the text for the "Create User" and "Continue" buttons in the `CreateUserWizardStep` and `CompleteWizardStep`, as well as if these buttons are rendered as Buttons, LinkButtons, or ImageButtons.

The colors, borders, fonts, and other visual elements are configurable through a host of style properties. The CreateUserWizard control itself has the common Web control style properties – `BackColor`, `BorderStyle`, `CssClass`, `Font`, and so on – and there are a number of style properties for defining the appearance for particular sections of the CreateUserWizard's interface. The `TextBoxStyle` property, for instance, defines the styles for the textboxes in the `CreateUserWizardStep`, while the `TitleTextStyle` property defines the style for the title ("Sign Up for Your New Account").

In addition to the appearance-related properties, there are a number of properties that affect the CreateUserWizard control's behavior. The `DisplayCancelButton` property, if set to True, displays a Cancel button next to the "Create User" button (the default value is False). If you display the Cancel button, be sure to also set the `CancelDestinationPageUrl` property, which specifies the page the user is sent to after clicking Cancel. As noted in the previous section, the Continue button in the `CompleteWizardStep`'s interface causes a postback, but leaves the visitor on the same page. To send the visitor to some other page after clicking the Continue button, simply specify the URL in the `ContinueDestinationPageUrl` property.

Let's update the `RegisterUser` CreateUserWizard control to show a Cancel button and to send the visitor to `Default.aspx` when the Cancel or Continue buttons are clicked. To accomplish this, set the `DisplayCancelButton` property to True and both the `CancelDestinationPageUrl` and `ContinueDestinationPageUrl` properties to "~/Default.aspx". Figure 14 shows the updated CreateUserWizard when viewed through a browser.

Figure 14: The `CreateUserWizardStep` Includes a Cancel Button (Click to view full-size image)

When a visitor enters a username, password, email address, and security question and answer and clicks "Create

User," a new user account is created and the visitor is logged in as that newly created user. Assuming that the person visiting the page is creating a new account for themselves, this is likely the desired behavior. However, you may want to allow Administrators to add new user accounts. In doing so, the user account would be created, but the Administrator would remain logged in as an Administrator (and not as the newly created account). This behavior can be modified through the Boolean `LoginCreatedUser` property.

User accounts in the Membership framework contain an approved flag; users who are not approved are unable to log into the site. By default, a newly created account is marked as approved, allowing the user to log into the site immediately. It is possible, however, to have new user accounts marked as unapproved. Perhaps you want an Administrator to manually approve new users before they can log in; or maybe you want to verify that the email address entered at signup is valid before permitting a user to log on. Whatever the case may be, you can have the newly created user account marked as unapproved by setting the CreateUserWizard control's `DisableCreatedUser` property to True (the default is False).

Other behavior-related properties of note include `AutoGeneratePassword` and `MailDefinition`. If the `AutoGeneratePassword` property is set to True, the `CreateUserWizardStep` does not display the "Password" and "Confirm Password" textboxes; instead, the newly-created user's password is automatically generated using the `Membership` class's `GeneratePassword` method. The `GeneratePassword` method constructs a password of a specified length and with a sufficient number of non-alphanumeric characters to satisfy the configured password strength requirements.

The `MailDefinition` property is useful if you want to send an email to the email address specified during the account creation process. The `MailDefinition` property includes a series of subproperties for defining information about the constructed email message. These subproperties include options like `Subject`, `Priority`, `IsBodyHtml`, `From`, `CC`, and `BodyFileName`. The `BodyFileName` property points to a text or HTML file that contains the body for the email message. The body supports two pre-defined placeholders: `<%UserName%>` and `<%Password%>`. These placeholders, if present in the `BodyFileName` file, will be replaced with the just-created user's name and password.

> **NOTE**
>
> The `CreateUserWizard` control's `MailDefinition` property just specifies details about the email message that is sent when a new account is created. It does not include any details on how the email message is actually sent (that is, whether an SMTP server or mail drop directory is used, any authentication information, and so on). These low-level details need to be defined in the `<system.net>` section in `Web.config`. For more information on these configuration settings and on sending email from ASP.NET 2.0 in general, refer to the FAQs at SystemNetMail.com and my article, Sending Email in ASP.NET 2.0.

Extending the CreateUserWizard's Behavior Using Event Handlers

The CreateUserWizard control raises a number of events during its workflow. For example, after a visitor enters their username, password, and other pertinent information and clicks the "Create User" button, the CreateUserWizard control raises its `CreatingUser` event. If there is a problem during the create process, the `CreateUserError` event is fired; however, if the user is successfully created, then the `CreatedUser` event is raised. There are additional CreateUserWizard control events that get raised, but these are the three most germane ones.

In certain scenarios we may want to tap into the CreateUserWizard workflow, which we can do by creating an event handler for the appropriate event. To illustrate this, let's enhance the `RegisterUser` CreateUserWizard control to include some custom validation on the username and password. In particular, let's enhance our CreateUserWizard so that usernames cannot contain leading or trailing spaces and the username cannot appear anywhere in the password. In short, we want to prevent someone from creating a username like "Scott ", or having a username/password combination like "Scott" and "Scott.1234".

To accomplish this we will create an event handler for the `CreatingUser` event to perform our extra validation

checks. If the supplied data is not valid we need to cancel the creation process. We also need to add a Label Web control to the page to display a message explaining that the username or password is invalid. Start by adding a Label control beneath the CreateUserWizard control, setting its `ID` property to `InvalidUserNameOrPasswordMessage` and its `ForeColor` property to `Red`. Clear out its `Text` property and set its `EnableViewState` and `Visible` properties to False.

```
<asp:Label runat="server" id="InvalidUserNameOrPasswordMessage"
     Visible="false" ForeColor="Red" EnableViewState="false">

</asp:Label>
```

Next, create an event handler for the CreateUserWizard control's `CreatingUser` event. To create an event handler, select the control in the Designer and then go to the Properties window. From there, click on the lightning bolt icon and then double-click the appropriate event to create the event handler.

Add the following code to the `CreatingUser` event handler:

```
protected void RegisterUser_CreatingUser(object sender, LoginCancelEventArgs e)
{
     string trimmedUserName = RegisterUser.UserName.Trim();
     if (RegisterUser.UserName.Length != trimmedUserName.Length)
     {
          // Show the error message
          InvalidUserNameOrPasswordMessage.Text = "The username cannot contain leading or trailing spaces.";
          InvalidUserNameOrPasswordMessage.Visible = true;

          // Cancel the create user workflow
          e.Cancel = true;
     }
     else
     {
          // Username is valid, make sure that the password does not contain the username

          if (RegisterUser.Password.IndexOf(RegisterUser.UserName, StringComparison.OrdinalIgnoreCase) >= 0)
          {
               // Show the error message
               InvalidUserNameOrPasswordMessage.Text = "The username may not appear anywhere in the
password.";
               InvalidUserNameOrPasswordMessage.Visible = true;
               // Cancel the create user workflow
               e.Cancel = true;
          }
     }
}
```

Note that the username and password entered into the CreateUserWizard control are available through its `UserName` and `Password` properties, respectively. We use these properties in the above event handler to determine whether the supplied username contains leading or trailing spaces and whether the username is found within the password. If either of these conditions is met, an error message is displayed in the `InvalidUserNameOrPasswordMessage` Label and the event handler's `e.Cancel` property is set to `true`. If `e.Cancel` is set to `true`, the CreateUserWizard short-circuits its workflow, effectively cancelling the user account creation process.

Figure 15 shows a screen shot of `CreatingUserAccounts.aspx` when the user enters a username with leading spaces.

Figure 15: Usernames with Leading or Trailing Spaces are not Permitted (Click to view full-size image)

> **NOTE**
>
> We will see an example of using the CreateUserWizard control's `CreatedUser` event in the *Storing Additional User Information* tutorial.

Summary

The `Membership` class's `CreateUser` method creates a new user account in the Membership framework. It does so by delegating the call to the configured Membership provider. In the case of the `SqlMembershipProvider`, the `CreateUser` method adds a record to the `aspnet_Users` and `aspnet_Membership` database tables.

While new user accounts can be created programmatically (as we saw in Step 5), a faster and easier approach is to use the CreateUserWizard control. This control renders a multi-step user interface for collecting user information and creating a new user in the Membership framework. Underneath the covers, this control uses the same `Membership.CreateUser` method as examined in Step 5, but the control creates the user interface, validation controls, and responds to user account creation errors without having to write a lick of code.

At this point we have the functionality in place to create new user accounts. However, the login page still is validating against those hard-coded credentials we specified back in the second tutorial. In the next tutorial we will update `Login.aspx` to validate the user's supplied credentials against the Membership framework.

Happy Programming!

Validating User Credentials Against the Membership User Store (C#)

9/16/2020 • 25 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will examine how to validate a user's credentials against the Membership user store using both programmatic means and the Login control. We will also look at how to customize the login control's appearance and behavior.

Introduction

In the preceding tutorial we looked at how to create a new user account in the Membership framework. We first looked at programmatically creating user accounts via the `Membership` class's `CreateUser` method, and then examined using the CreateUserWizard Web control. However, the login page currently validates the supplied credentials against a hard-coded list of username and password pairs. We need to update the login page's logic so that it validates credentials against the Membership framework's user store.

Much like with creating user accounts, credentials can be validated programmatically or declaratively. The Membership API includes a method for programmatically validating a user's credentials against the user store. And ASP.NET ships with the Login Web control, which renders a user interface with textboxes for the username and password and a button to log in.

In this tutorial we will examine how to validate a user's credentials against the Membership user store using both programmatic means and the Login control. We will also look at how to customize the login control's appearance and behavior. Let's get started!

Step 1: Validating Credentials Against the Membership User Store

For web sites that use forms authentication, a user logs on to the website by visiting a login page and entering their credentials. These credentials are then compared against the user store. If they are valid, then the user is granted a forms authentication ticket, which is a security token that indicates the identity and authenticity of the visitor.

To validate a user against the Membership framework, use the `Membership` class's `ValidateUser` method. The `ValidateUser` method takes in two input parameters - *`username`* and *`password`* - and returns a Boolean value indicating whether the credentials were valid. Like with the `CreateUser` method we examined in the previous tutorial, the `ValidateUser` method delegates the actual validation to the configured Membership provider.

The `SqlMembershipProvider` validates the supplied credentials by obtaining the specified user's password via the `aspnet_Membership_GetPasswordWithFormat` stored procedure. Recall that the `SqlMembershipProvider` stores users' passwords using one of three formats: clear, encrypted, or hashed. The `aspnet_Membership_GetPasswordWithFormat` stored procedure returns the password in its raw format. For encrypted or hashed passwords, the `SqlMembershipProvider` transforms the *`password`* value passed into the `ValidateUser` method into its equivalent encrypted or hashed state and then compares it with what was returned from the database. If the password stored in the database matches the formatted password entered by the user, the credentials are valid.

Let's update our login page (~/`Login.aspx`) so that it validates the supplied credentials against the Membership

framework user store. We created this login page back in the *An Overview of Forms Authentication* tutorial, creating an interface with two TextBoxes for the username and password, a Remember Me checkbox, and a Login button (see Figure 1). The code validates the entered credentials against a hard-coded list of username and password pairs (Scott/password, Jisun/password, and Sam/password). In the *Forms Authentication Configuration and Advanced Topics* tutorial we updated the login page's code to store additional information in the forms authentication ticket's `UserData` property.

Figure 1: The Login Page's Interface Includes Two TextBoxes, a CheckBoxList, and a Button (Click to view full-size image)

The login page's user interface can remain unchanged, but we need to replace the Login button's `Click` event handler with code that validates the user against the Membership framework user store. Update the event handler so that its code appears as follows:

```
protected void LoginButton_Click(object sender, EventArgs e)
{
    // Validate the user against the Membership framework user store
    if (Membership.ValidateUser(UserName.Text, Password.Text))
    {
        // Log the user into the site
        FormsAuthentication.RedirectFromLoginPage(UserName.Text, RememberMe.Checked);
    }
    // If we reach here, the user's credentials were invalid
    InvalidCredentialsMessage.Visible = true;
}
```

This code is remarkably simple. We start by calling the `Membership.ValidateUser` method, passing in the supplied username and password. If that method returns true, then the user is signed into the site via the `FormsAuthentication` class's RedirectFromLoginPage method. (As we discussed in the *An Overview of Forms Authentication* tutorial, the `FormsAuthentication.RedirectFromLoginPage` creates the forms authentication ticket and then redirects the user to the appropriate page.) If the credentials are invalid, however, the `InvalidCredentialsMessage` Label is displayed, informing the user that their username or password was incorrect.

That's all there is to it!

To test that the login page works as expected, attempt to login with one of the user accounts you created in the preceding tutorial. Or, if you have not yet created an account, go ahead and create one from the `~/Membership/CreatingUserAccounts.aspx` page.

> **NOTE**
> When the user enters her credentials and submits the login page form, the credentials, including her password, are transmitted over the Internet to the web server in *plain text*. That means any hacker sniffing the network traffic can see the username and password. To prevent this, it is essential to encrypt the network traffic by using Secure Socket Layers (SSL). This will ensure that the credentials (as well as the entire page's HTML markup) are encrypted from the moment they leave the browser until they are received by the web server.

How the Membership Framework Handles Invalid Login Attempts

When a visitor reaches the login page and submits their credentials, their browser makes an HTTP request to the login page. If the credentials are valid, the HTTP response includes the authentication ticket in a cookie. Therefore, a hacker attempting to break into your site could create a program that exhaustively sends HTTP requests to the login page with a valid username and a guess at the password. If the password guess is correct, the login page will return the authentication ticket cookie, at which point the program knows it has stumbled upon a valid username/password pair. Through brute force, such a program might be able to stumble upon a user's password, especially if the password is weak.

To prevent such brute force attacks, the Membership framework locks out a user if there are a certain number of unsuccessful login attempts within a certain period of time. The exact parameters are configurable through the following two Membership provider configuration settings:

- `maxInvalidPasswordAttempts` - specifies how many invalid password attempts are allowed for the user within the time period before the account is locked out. The default value is 5.
- `passwordAttemptWindow` - indicates the time period in minutes during which the specified number of invalid login attempts will cause the account to be locked out. The default value is 10.

If a user has been locked out, she cannot login until an administrator unlocks her account. When a user is locked out, the `ValidateUser` method will *always* return `false`, even if valid credentials are supplied. While this behavior lessens the likelihood that a hacker will break into your site through brute force methods, it can end up locking out a valid user who has simply forgotten her password or accidentally has the Caps Lock on or is having a bad typing day.

Unfortunately, there is no built-in tool for unlocking a user account. In order to unlock an account, you can modify the database directly - change the `IsLockedOut` field in the `aspnet_Membership` table for the appropriate user account - or create a web-based interface that lists locked out accounts with options to unlock them. We will examine creating administrative interfaces for accomplishing common user account- and role-related tasks in a future tutorial.

> **NOTE**
> One downside of the `ValidateUser` method is that when the supplied credentials are invalid, it does not provide any explanation as to why. The credentials may be invalid because there is no matching username/password pair in the user store, or because the user has not yet been approved, or because the user has been locked out. In Step 4 we will see how to show a more detailed message to the user when their login attempt fails.

Step 2: Collecting Credentials through the Login Web Control

The Login Web control renders a default user interface very similar to the one we created back in the *An Overview of Forms Authentication* tutorial. Using the Login control saves us the work of having to create the

interface to collect the visitor's credentials. Moreover, the Login control automatically signs in the user (assuming the submitted credentials are valid), thereby saving us from having to write any code.

Let's update `Login.aspx`, replacing the manually created interface and code with a Login control. Start by removing the existing markup and code in `Login.aspx`. You may delete it outright, or simply comment it out. To comment out declarative markup, surround it with the `<%--` and `--%>` delimiters. You can enter these delimiters manually, or, as Figure 2 shows, you may select the text to comment out and then click the Comment out the selected lines icon in the Toolbar. Similarly, you can use the Comment out the selected lines icon to comment out the selected code in the code-behind class.

Figure 2: Comment Out the Existing Declarative Markup and Source Code in `Login.aspx` (Click to view full-size image)

> **NOTE**
>
> The Comment out the selected lines icon is not available when viewing the declarative markup in Visual Studio 2005. If you are not using Visual Studio 2008 you will need to manually add the `<%--` and `--%>` delimiters.

Next, drag a Login control from the Toolbox on to the page and set its `ID` property to `myLogin`. At this point your screen should look similar to Figure 3. Note that the Login control's default interface includes TextBox controls for the username and password, a Remember me next time CheckBox, and a Log In Button. There are also `RequiredFieldValidator` controls for the two TextBoxes.

Figure 3: Add a Login Control to the Page (Click to view full-size image)

And we're done! When the Login control's Log In button is clicked, a postback will occur and the Login control will call the `Membership.ValidateUser` method, passing in the entered username and password. If the credentials are invalid, the Login control displays a message stating such. If, however, the credentials are valid, then the Login control creates the forms authentication ticket and redirects the user to the appropriate page.

The Login control uses four factors to determine the appropriate page to redirect the user to upon a successful login:

- Whether the Login control is on the login page as defined by `loginUrl` setting in the forms authentication configuration; this setting's default value is `Login.aspx`
- The presence of a `ReturnUrl` querystring parameter
- The value of the Login control's `DestinationUrl` property
- The `defaultUrl` value specified in the forms authentication configuration settings; this setting's default value is `Default.aspx`

Figure 4 depicts the how the Login control uses these four parameters to arrive at its appropriate page decision.

Figure 4: Add a Login Control to the Page (Click to view full-size image)

Take a moment to test out the Login control by visiting the site through a browser and logging in as an existing user in the Membership framework.

The Login control's rendered interface is highly configurable. There are a number of properties that influence its appearance; what's more, the Login control can be converted into a template for precise control over the layout the user interface elements. The remainder of this step examines how to customize the appearance and layout.

Customizing the Login Control's Appearance

The Login control's default property settings render a user interface with a title (Log In), TextBox and Label controls for the username and password inputs, a Remember me next time CheckBox, and a Log In button. The appearances of these elements are all configurable through the Login control's numerous properties. Furthermore, additional user interface elements - such as a link to a page to create a new user account - can be added by setting a property or two.

Let's spend a few moments to gussy up the appearance of our Login control. Since the `Login.aspx` page already has text at the top of the page that says Login, the Login control's title is superfluous. Therefore, clear out the `TitleText` property value in order to remove the Login control's title.

The User Name: and Password: Labels to the left of the two TextBox controls can be customized through the `UserNameLabelText` and `PasswordLabelText` properties, respectively. Let's change the User Name: Label to read Username:. The Label and TextBox styles are configurable through the `LabelStyle` and `TextBoxStyle` properties, respectively.

The Remember me next time CheckBox's Text property can be set through the Login control's `RememberMeText property`, and its default checked state is configurable through the `RememberMeSet property` (which defaults to False). Go ahead and set the `RememberMeSet` property to True so that the Remember me next time CheckBox will be checked by default.

The Login control offers two properties for adjusting the layout of its user interface controls. The `TextLayout property` indicates whether the Username: and Password: Labels appear to the left of their

corresponding TextBoxes (the default), or above them. The `Orientation property` indicates whether the username and password inputs are situated vertically (one above the other) or horizontally. I am going to leave these two properties set to their defaults, but I encourage you to try setting these two properties to their non-default values to see the resulting effect.

> **NOTE**
>
> In the next section, Configuring the Login Control's Layout, we will look at using templates to define the precise layout of the Layout control's user interface elements.

Wrap up the Login control's property settings by setting the `CreateUserText` and `CreateUserUrl` properties to Not registered yet? Create an account! and `~/Membership/CreatingUserAccounts.aspx`, respectively. This adds a hyperlink to the Login control's interface pointing to the page we created in the preceding tutorial. The Login control's `HelpPageText` and `HelpPageUrl` properties and `PasswordRecoveryText` and `PasswordRecoveryUrl` properties work in the same manner, rendering links to a help page and a password recovery page.

After making these property changes, your Login control's declarative markup and appearance should look similar to that shown in Figure 5.

Figure 5: The Login Control's Properties' Values Dictate Its Appearance (Click to view full-size image)

Configuring the Login Control's Layout

The Login Web control's default user interface lays out the interface in an HTML `<table>`. But what if we need finer control over the rendered output? Maybe we want to replace the `<table>` with a series of `<div>` tags. Or what if our application requires additional credentials for authentication? Many financial websites, for instance, require users to supply not only a username and password, but also a Personal Identification Number (PIN), or other identifying information. Whatever the reasons may be, it is possible to convert the Login control into a template, from which we can explicitly define the interface's declarative markup.

We need to do two things in order to update the Login control to collect additional credentials:

1. Update the Login control's interface to include Web control(s) to collect the additional credentials.
2. Override the Login control's internal authentication logic so that a user is only authenticated if their username

and password is valid and their additional credentials are valid, too.

To accomplish the first task, we need to convert the Login control into a template and add the necessary Web controls. As for the second task, the Login control's authentication logic can be superseded by creating an event handler for the control's `Authenticate` event.

Let's update the Login control so that it prompts users for their username, password, and email address and only authenticates the user if the email address supplied matches their email address on file. We first need to convert the Login control's interface to a template. From the Login control's Smart Tag, choose the Convert to template option.

Figure 6: Convert the Login Control to a Template (Click to view full-size image)

> **NOTE**
>
> To revert the Login control to its pre-template version, click the Reset link from the control's Smart Tag.

Converting the Login control to a template adds a `LayoutTemplate` to the control's declarative markup with HTML elements and Web controls defining the user interface. As Figure 7 shows, converting the control to a template removes a number of properties from the Properties window, such as `TitleText`, `CreateUserUrl`, and so forth, since these property values are ignored when using a template.

Figure 7: Fewer Properties are Available When the Login Control is Converted to a Template (Click to view full-size image)

The HTML markup in the `LayoutTemplate` may be modified as needed. Likewise, feel free to add any new Web controls to the template. However, it is important that Login control's core Web controls remain in the template and keep their assigned `ID` values. In particular, do not remove or rename the `UserName` or `Password` TextBoxes, the `RememberMe` CheckBox, the `LoginButton` Button, the `FailureText` Label, or the `RequiredFieldValidator` controls.

To collect the visitor's email address, we need to add a TextBox to the template. Add the following declarative markup between the table row (`<tr>`) that contains the `Password` TextBox and the table row that holds the Remember me next time CheckBox:

```
<tr>
 <td align="right">
 <asp:Label ID="EmailLabel" runat="server" AssociatedControlID="Email">Email:</asp:Label>
 </td>
 <td>
 <asp:TextBox ID="Email" runat="server"></asp:TextBox>
 <asp:RequiredFieldValidator ID="EmailRequired" runat="server"
 ControlToValidate="Email" ErrorMessage="Email is required."
 ToolTip="Email is required." ValidationGroup="myLogin">*</asp:RequiredFieldValidator>
 </td>
</tr>
```

After adding the `Email` TextBox, visit the page through a browser. As Figure 8 shows, the Login control's user interface now includes a third textbox.

Figure 8: The Login Control Now Includes a Textbox for the User's Email Address (Click to view full-size image)

At this point, the Login control is still using the `Membership.ValidateUser` method to validate the supplied credentials. Correspondingly, the value entered into the `Email` TextBox has no bearing on whether the user can log in. In Step 3 we will look at how to override the Login control's authentication logic so that the credentials are only considered valid if the username and password are valid and the supplied email address matches up with the email address on file.

Step 3: Modifying the Login Control's Authentication Logic

When a visitor supplies her credentials and clicks the Log In button, a postback ensues and the Login control progresses through its authentication workflow. The workflow starts by raising the `LoggingIn` event. Any event handlers associated with this event may cancel the log in operation by setting the `e.Cancel` property to `true`.

If the log in operation is not cancelled, the workflow progresses by raising the `Authenticate` event. If there is an event handler for the `Authenticate` event, then it is responsible for determining whether the supplied credentials are valid or not. If no event handler is specified, the Login control uses the `Membership.ValidateUser` method to determine the validity of the credentials.

If the supplied credentials are valid, then the forms authentication ticket is created, the `LoggedIn` event is raised, and the user is redirected to the appropriate page. If, however, the credentials are deemed invalid, then the `LoginError` event is raised and a message is displayed informing the user that their credentials were invalid. By default, on failure the Login control simply sets its `FailureText` Label control's Text property to a failure message (Your login attempt was not successful. Please try again). However, if the Login control's `FailureAction` property is set to `RedirectToLoginPage`, then the Login control issues a `Response.Redirect` to the login page appending the querystring parameter `loginfailure=1` (which causes the Login control to display the failure message).

Figure 9 offers a flow chart of the authentication workflow.

Figure 9: The Login Control's Authentication Workflow (Click to view full-size image)

> **NOTE**
> If you are wondering when you would use the `FailureAction`'s `RedirectToLogin` page option, consider the following scenario. Right now our `Site.master` master page currently has the text, Hello, stranger displayed in the left column when visited by an anonymous user, but imagine that we wanted to replace that text with a Login control. This would allow an anonymous user to log in from any page on the site, instead of requiring them to visit the login page directly. However, if a user was unable to log in via the Login control rendered by the master page, it might make sense to redirect them to the login page (`Login.aspx`) because that page likely includes additional instructions, links, and other help - such as links to create a new account or retrieve a lost password - that were not added to the master page.

Creating the `Authenticate` Event Handler

In order to plug in our custom authentication logic, we need to create an event handler for the Login control's `Authenticate` event. Creating an event handler for the `Authenticate` event will generate the following event handler definition:

```
protected void myLogin_Authenticate(object sender, AuthenticateEventArgs e)
{
}
```

As you can see, the `Authenticate` event handler is passed an object of type `AuthenticateEventArgs` as its second input parameter. The `AuthenticateEventArgs` class contains a Boolean property named `Authenticated` that is used to specify whether the supplied credentials are valid. Our task, then, is to write code here that determines whether the supplied credentials are valid or not, and to set the `e.Authenticate` property accordingly.

Determining and Validating the Supplied Credentials

Use the Login control's `UserName` and `Password` properties to determine the username and password credentials entered by the user. In order to determine the values entered into any additional Web controls (such as the

`Email` TextBox we added in the previous step), use `LoginControlID` `.FindControl` ("`controlID`") to obtain a programmatic reference to the Web control in the template whose `ID` property is equal to `controlID`. For example, to get a reference to the `Email` TextBox, use the following code:

```
TextBox EmailTextBox = myLogin.FindControl("Email") as TextBox;
```

In order to validate the user's credentials we need to do two things:

1. Ensure that the provided username and password are valid
2. Ensure that email address entered matches the email address on file for the user attempting to log in

To accomplish the first check we can simply use the `Membership.ValidateUser` method like we saw in Step 1. For the second check, we need to determine the user's email address so that we can compare it to the email address they entered into the TextBox control. To get information about a particular user, use the `Membership` class's `GetUser` method.

The `GetUser` method has a number of overloads. If used without passing in any parameters, it returns information about the currently logged in user. To get information about a particular user, call `GetUser` passing in their username. Either way, `GetUser` returns a `MembershipUser` object, which has properties like `UserName`, `Email`, `IsApproved`, `IsOnline`, and so on.

The following code implements these two checks. If both pass, then `e.Authenticate` is set to `true`, otherwise it is assigned `false`.

```
protected void myLogin_Authenticate(object sender, AuthenticateEventArgs e)
{
    // Get the email address entered
    TextBox EmailTextBox = myLogin.FindControl("Email") as TextBox;
    string email = EmailTextBox.Text.Trim();

    // Verify that the username/password pair is valid
    if (Membership.ValidateUser(myLogin.UserName, myLogin.Password))
    {
        // Username/password are valid, check email
        MembershipUser usrInfo = Membership.GetUser(myLogin.UserName);
        if (usrInfo != null && string.Compare(usrInfo.Email, email, true) == 0)
        {
            // Email matches, the credentials are valid
            e.Authenticated = true;
        }
        else
        {
            // Email address is invalid...
            e.Authenticated = false;
        }
    }
    else
    {
        // Username/password are not valid...
        e.Authenticated = false;
    }
}
```

With this code in place, attempt to log in as a valid user, entering the correct username, password, and email address. Try it again, but this time purposefully use an incorrect email address (see Figure 10). Finally, try it a third time using a non-existent username. In the first case you should be successfully logged on to the site, but in the last two cases you should see the Login control's invalid credentials message.

Figure 10: Tito Cannot Log In When Supplying an Incorrect Email Address (Click to view full-size image)

> **NOTE**
>
> As discussed in the How the Membership Framework Handles Invalid Login Attempts section in Step 1, when the `Membership.ValidateUser` method is called and passed invalid credentials, it keeps track of the invalid login attempt and locks out the user if they exceed a certain threshold of invalid attempts within a specified time window. Since our custom authentication logic calls the `ValidateUser` method, an incorrect password for a valid username will increment the invalid login attempt counter, but this counter is not incremented in the case where the username and password are valid, but the email address is incorrect. Chances are, this behavior is suitable, since it's unlikely that a hacker will know the username and password, but have to use brute force techniques to determine the user's email address.

Step 4: Improving the Login Control's Invalid Credentials Message

When a user attempts to log on with invalid credentials, the Login control displays a message explaining that the login attempt was unsuccessful. In particular, the control displays the message specified by its `FailureText` property, which has a default value of Your login attempt was not successful. Please try again.

Recall that there are many reasons why a user's credentials may be invalid:

- The username may not exist
- The username exists, but the password is invalid
- The username and password are valid, but the user is not yet approved
- The username and password are valid, but the user is locked out (most likely because they exceeded the number of invalid login attempts within the specified time frame)

And there may be other reasons when using custom authentication logic. For example, with the code we wrote in Step 3, the username and password may be valid, but the email address may be incorrect.

Regardless of why the credentials are invalid, the Login control displays the same error message. This lack of feedback can be confusing for a user whose account has not yet been approved or who has been locked out. With a little bit of work, though, we can have the Login control display a more appropriate message.

Whenever a user attempts to login with invalid credentials the Login control raises its `LoginError` event. Go ahead and create an event handler for this event, and add the following code:

```
protected void myLogin_LoginError(object sender, EventArgs e)
{
    // Determine why the user could not login...
    myLogin.FailureText = "Your login attempt was not successful. Please try again.";

    // Does there exist a User account for this user?
    MembershipUser usrInfo = Membership.GetUser(myLogin.UserName);
    if (usrInfo != null)
    {
        // Is this user locked out?
        if (usrInfo.IsLockedOut)
        {
            myLogin.FailureText = "Your account has been locked out because of too many invalid login
attempts. Please contact the administrator to have your account unlocked.";
        }
        else if (!usrInfo.IsApproved)
        {
            myLogin.FailureText = "Your account has not yet been approved. You cannot login until an
administrator has approved your account.";
        }
    }
}
```

The above code starts by setting the Login control's `FailureText` property to the default value (Your login attempt was not successful. Please try again). It then checks to see if the username supplied maps to an existing user account. If so, it consults the resulting `MembershipUser` object's `IsLockedOut` and `IsApproved` properties to determine if the account has been locked out or has not yet been approved. In either case, the `FailureText` property is updated to a corresponding value.

To test this code, purposefully attempt to log in as an existing user, but use an incorrect password. Do this five times in a row within a 10 minute time frame and the account will be locked out. As Figure 11 shows, subsequent login attempts will always fail (even with the correct password), but will now display the more descriptive Your account has been locked out because of too many invalid login attempts. Please contact the administrator to have your account unlocked message.

Figure 11: Tito Performed Too Many Invalid Login Attempts and Has Been Locked Out (Click to view full-size image)

Summary

Prior this tutorial, our login page validated the supplied credentials against a hard-coded list of username/password pairs. In this tutorial, we updated the page to validate credentials against the Membership framework. In Step 1 we looked at using the `Membership.ValidateUser` method programmatically. In Step 2 we replaced our manually created user interface and code with the Login control.

The Login control renders a standard login user interface and automatically validates the user's credentials against the Membership framework. Moreover, in the event of valid credentials, the Login control signs the user in via forms authentication. In short, a fully functional login user experience is available by simply dragging the Login control onto a page, no extra declarative markup or code necessary. What's more, the Login control is highly customizable, allowing for a fine degree of control over both the rendered user interface and authentication logic.

At this point visitors to our website can create a new user account and log into the site, but we have yet to look at restricting access to pages based on the authenticated user. Currently, any user, authenticated or anonymous, can view any page on our site. Along with controlling access to our site's pages on a user-by-user basis, we might have certain pages whose functionality depends on the user. The next tutorial looks at how to limit access and in-page functionality based on the logged in user.

Happy Programming!

> In this tutorial we will look at limiting access to pages and restricting page-level functionality through a variety of techniques.

Introduction

Most web applications that offer user accounts do so in part to restrict certain visitors from accessing certain pages within the site. In most online messageboard sites, for example, all users - anonymous and authenticated - are able to view the messageboard's posts, but only authenticated users can visit the web page to create a new post. And there may be administrative pages that are only accessible to a particular user (or a particular set of users). Moreover, page-level functionality can differ on a user-by-user basis. When viewing a list of posts, authenticated users are shown an interface for rating each post, whereas this interface is not available to anonymous visitors.

ASP.NET makes it easy to define user-based authorization rules. With just a bit of markup in `Web.config`, specific web pages or entire directories can be locked down so that they are only accessible to a specified subset of users. Page-level functionality can be turned on or off based on the currently logged in user through programmatic and declarative means.

In this tutorial we will look at limiting access to pages and restricting page-level functionality through a variety of techniques. Let's get started!

A Look at the URL Authorization Workflow

As discussed in the *An Overview of Forms Authentication* tutorial, when the ASP.NET runtime processes a request for an ASP.NET resource the request raises a number of events during its lifecycle. *HTTP Modules* are managed classes whose code is executed in response to a particular event in the request lifecycle. ASP.NET ships with a number of HTTP Modules that perform essential tasks behind the scenes.

One such HTTP Module is `FormsAuthenticationModule`. As discussed in previous tutorials, the primary function of the `FormsAuthenticationModule` is to determine the identity of the current request. This is accomplished by inspecting the forms authentication ticket, which is either located in a cookie or embedded within the URL. This identification takes place during the `AuthenticateRequest` event.

Another important HTTP Module is the `UrlAuthorizationModule`, which is raised in response to the `AuthorizeRequest` event (which happens after the `AuthenticateRequest` event). The `UrlAuthorizationModule` examines configuration markup in `Web.config` to determine whether the current identity has authority to visit the specified page. This process is referred to as *URL authorization*.

We'll examine the syntax for the URL authorization rules in Step 1, but first let's look at what the `UrlAuthorizationModule` does depending on whether the request is authorized or not. If the `UrlAuthorizationModule` determines that the request is authorized, then it does nothing, and the request continues through its lifecycle. However, if the request is *not* authorized, then the `UrlAuthorizationModule` aborts the lifecycle and instructs the `Response` object to return an HTTP 401 Unauthorized status. When using forms authentication this HTTP 401 status is never returned to the client because if the `FormsAuthenticationModule`

detects an HTTP 401 status is modifies it to an HTTP 302 Redirect to the login page.

Figure 1 illustrates the workflow of the ASP.NET pipeline, the `FormsAuthenticationModule`, and the `UrlAuthorizationModule` when an unauthorized request arrives. In particular, Figure 1 shows a request by an anonymous visitor for `ProtectedPage.aspx`, which is a page that denies access to anonymous users. Since the visitor is anonymous, the `UrlAuthorizationModule` aborts the request and returns an HTTP 401 Unauthorized status. The `FormsAuthenticationModule` then converts the 401 status into a 302 Redirect to login page. After the user is authenticated via the login page, he is redirected to `ProtectedPage.aspx`. This time the `FormsAuthenticationModule` identifies the user based on his authentication ticket. Now that the visitor is authenticated, the `UrlAuthorizationModule` permits access to the page.

Figure 1: The Forms Authentication and URL Authorization Workflow (Click to view full-size image)

Figure 1 depicts the interaction that occurs when an anonymous visitor attempts to access a resource that is not available to anonymous users. In such a case, the anonymous visitor is redirected to the login page with the page she attempted to visit specified in the querystring. Once the user has successfully logged on, she will be automatically redirected back to the resource she was initially attempting to view.

When the unauthorized request is made by an anonymous user, this workflow is straightforward and is easy for the visitor to understand what has happened and why. But keep in mind that the `FormsAuthenticationModule` will redirect *any* unauthorized user to the login page, even if the request is made by an authenticated user. This can result in a confusing user experience if an authenticated user attempts to visit a page for which she lacks authority.

Imagine that our website had its URL authorization rules configured such that the ASP.NET page `OnlyTito.aspx` was accessibly only to Tito. Now, imagine that Sam visits the site, logs on, and then attempts to visit `OnlyTito.aspx`. The `UrlAuthorizationModule` will halt the request lifecycle and return an HTTP 401 Unauthorized status, which the `FormsAuthenticationModule` will detect and then redirect Sam to the login page. Since Sam has already logged in, though, she may wonder why she has been sent back to the login page. She might reason that her login credentials were lost somehow, or that she entered invalid credentials. If Sam reenters her credentials from the login page she will be logged on (again) and redirected to `OnlyTito.aspx`. The `UrlAuthorizationModule`

will detect that Sam cannot visit this page and she will be returned to the login page.

Figure 2 depicts this confusing workflow.

Figure 2: The Default Workflow Can Lead to a Confusing Cycle (Click to view full-size image)

The workflow illustrated in Figure 2 can quickly befuddle even the most computer savvy visitor. We will look at ways to prevent this confusing cycle in Step 2.

> **NOTE**
>
> ASP.NET uses two mechanisms to determine whether the current user can access a particular web page: URL authorization and file authorization. File authorization is implemented by the `FileAuthorizationModule`, which determines authority by consulting the requested file(s) ACLs. File authorization is most commonly used with Windows authentication because ACLs are permissions that apply to Windows accounts. When using forms authentication, all operating system- and file system-level requests are executed by the same Windows account, regardless of the user visiting the site. Since this tutorial series focuses on forms authentication, we will not be discussing file authorization.

The Scope of URL Authorization

The `UrlAuthorizationModule` is managed code that is part of the ASP.NET runtime. Prior to version 7 of Microsoft's Internet Information Services (IIS) web server, there was a distinct barrier between IIS's HTTP pipeline and the ASP.NET runtime's pipeline. In short, in IIS 6 and earlier, ASP.NET's `UrlAuthorizationModule` only executes when a request is delegated from IIS to the ASP.NET runtime. By default, IIS processes static content itself - like HTML pages and CSS, JavaScript, and image files - and only hands off requests to the ASP.NET runtime when a page with an extension of `.aspx`, `.asmx`, or `.ashx` is requested.

IIS 7, however, allows for integrated IIS and ASP.NET pipelines. With a few configuration settings you can setup IIS 7 to invoke the `UrlAuthorizationModule` for *all* requests, meaning that URL authorization rules can be defined for files of any type. Additionally, IIS 7 includes its own URL authorization engine. For more information on ASP.NET integration and IIS 7's native URL authorization functionality, see Understanding IIS7 URL Authorization. For a more in-depth look at ASP.NET and IIS 7 integration, pick up a copy of Shahram Khosravi's book,

Professional IIS 7 and ASP.NET Integrated Programming (ISBN: 978-0470152539).

In a nutshell, in versions prior to IIS 7, URL authorization rules are only applied to resources handled by the ASP.NET runtime. But with IIS 7 it is possible to use IIS's native URL authorization feature or to integrate ASP.NET's `UrlAuthorizationModule` into IIS's HTTP pipeline, thereby extending this functionality to all requests.

> **NOTE**
> There are some subtle yet important differences in how ASP.NET's `UrlAuthorizationModule` and IIS 7's URL authorization feature process the authorization rules. This tutorial does not examine IIS 7's URL authorization functionality or the differences in how it parses authorization rules compared to the `UrlAuthorizationModule`. For more information on these topics, refer to the IIS 7 documentation on MSDN or at www.iis.net.

Step 1: Defining URL Authorization Rules in `Web.config`

The `UrlAuthorizationModule` determines whether to grant or deny access to a requested resource for a particular identity based on the URL authorization rules defined in the application's configuration. The authorization rules are spelled out in the `<authorization>` element in the form of `<allow>` and `<deny>` child elements. Each `<allow>` and `<deny>` child element can specify:

- A particular user
- A comma-delimited list of users
- All anonymous users, denoted by a question mark (?)
- All users, denoted by an asterisk (*)

The following markup illustrates how to use the URL authorization rules to allow users Tito and Scott and deny all others:

```
<authorization>
 <allow users="Tito, Scott" />
 <deny users="*" />
</authorization>
```

The `<allow>` element defines what users are permitted - Tito and Scott - while the `<deny>` element instructs that *all* users are denied.

> **NOTE**
> The `<allow>` and `<deny>` elements can also specify authorization rules for roles. We will examine role-based authorization in a future tutorial.

The following setting grants access to anyone other than Sam (including anonymous visitors):

```
<authorization>
 <deny users="Sam" />
</authorization>
```

To allow only authenticated users, use the following configuration, which denies access to all anonymous users:

```
<authorization>
 <deny users="?" />
</authorization>
```

The authorization rules are defined within the `<system.web>` element in `Web.config` and apply to all of the ASP.NET resources in the web application. Oftentimes, an application has different authorization rules for different sections. For example, at an eCommerce site, all visitors may peruse the products, see product reviews, search the catalog, and so on. However, only authenticated users may reach the checkout or the pages to manage one's shipping history. Moreover, there may be portions of the site that are only accessible by select users, such as site administrators.

ASP.NET makes it easy to define different authorization rules for different files and folders in the site. The authorization rules specified in the root folder's `Web.config` file apply to all ASP.NET resources in the site. However, these default authorization settings can be overridden for a particular folder by adding a `Web.config` with an `<authorization>` section.

Let's update our website so that only authenticated users can visit the ASP.NET pages in the `Membership` folder. To accomplish this we need to add a `Web.config` file to the `Membership` folder and set its authorization settings to deny anonymous users. Right-click the `Membership` folder in the Solution Explorer, choose the Add New Item menu from the context menu, and add a new Web Configuration File named `Web.config`.

Figure 3: Add a `Web.config` File to the `Membership` Folder (Click to view full-size image)

At this point your project should contain two `Web.config` files: one in the root directory and one in the `Membership` folder.

Figure 4: Your Application Should Now Contain Two `Web.config` Files (Click to view full-size image)

Update the configuration file in the `Membership` folder so that it prohibits access to anonymous users.

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 <authorization>
 <deny users="?" />
 </authorization>
 </system.web>
</configuration>
```

That's all there is to it!

To test out this change, visit the homepage in a browser and make sure you are logged out. Since the default behavior of an ASP.NET application is to allow all visitors, and since we didn't make any authorization modifications to the root directory's `Web.config` file, we are able to visit the files in the root directory as an anonymous visitor.

Click on the Creating User Accounts link found in the left column. This will take you to the `~/Membership/CreatingUserAccounts.aspx`. Since the `Web.config` file in the `Membership` folder defines authorization rules to prohibit anonymous access, the `UrlAuthorizationModule` aborts the request and returns an HTTP 401 Unauthorized status. The `FormsAuthenticationModule` modifies this to a 302 Redirect status, sending us to the login page. Note that the page we were attempting to access (`CreatingUserAccounts.aspx`) is passed to the login page via the `ReturnUrl` querystring parameter.

Figure 5: Since the URL Authorization Rules Prohibit Anonymous Access, We are Redirected to the Login Page (Click to view full-size image)

Upon successfully logging in, we are redirected to the `CreatingUserAccounts.aspx` page. This time the `UrlAuthorizationModule` permits access to the page because we are no longer anonymous.

Applying URL Authorization Rules to a Specific Location

The authorization settings defined in the `<system.web>` section of `Web.config` apply to all of the ASP.NET resources in that directory and its subdirectories (until otherwise overridden by another `Web.config` file). In some cases, though, we may want all ASP.NET resources in a given directory to have a particular authorization configuration except for one or two specific pages. This can be achieved by adding a `<location>` element in `Web.config`, pointing it to the file whose authorization rules differ, and defining its unique authorization rules therein.

To illustrate using the `<location>` element to override the configuration settings for a specific resource, let's customize the authorization settings so that only Tito can visit `CreatingUserAccounts.aspx`. To accomplish this, add a `<location>` element to the `Membership` folder's `Web.config` file and update its markup so that it looks like the following:

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 <authorization>
 <deny users="?" />
 </authorization>
 </system.web>

 <location path="CreatingUserAccounts.aspx">
 <system.web>
 <authorization>
 <allow users="Tito" />
 <deny users="*" />
 </authorization>
 </system.web>
 </location>
</configuration>
```

The `<authorization>` element in `<system.web>` defines the default URL authorization rules for ASP.NET resources in the `Membership` folder and its subfolders. The `<location>` element allows us to override these rules for a particular resource. In the above markup the `<location>` element references the `CreatingUserAccounts.aspx` page and specifies its authorization rules such as to allow Tito, but deny everyone else.

To test out this authorization change, start by visiting the website as an anonymous user. If you attempt to visit any page in the `Membership` folder, such as `UserBasedAuthorization.aspx`, the `UrlAuthorizationModule` will deny the request and you will be redirected to the login page. After logging in as, say, Scott, you can visit any page in the `Membership` folder *except* for `CreatingUserAccounts.aspx`. Attempting to visit `CreatingUserAccounts.aspx` logged on as anyone but Tito will result in an unauthorized access attempt, redirecting you back to the login page.

> **NOTE**
> The `<location>` element must appear outside of the configuration's `<system.web>` element. You need to use a separate `<location>` element for each resource whose authorization settings you want to override.

A Look at How the `UrlAuthorizationModule` Uses the Authorization Rules to Grant or Deny Access

The `UrlAuthorizationModule` determines whether to authorize a particular identity for a particular URL by analyzing the URL authorization rules one at a time, starting from the first one and working its way down. As soon as a match is found, the user is granted or denied access, depending on if the match was found in an `<allow>` or `<deny>` element. **If no match is found, the user is granted access.** Consequently, if you want to restrict access, it is imperative that you use a `<deny>` element as the last element in the URL authorization configuration. **If you omit a `<deny>` element, all users will be granted access.**

To better understand the process used by the `UrlAuthorizationModule` to determine authority, consider the example URL authorization rules we looked at earlier in this step. The first rule is an `<allow>` element that allows access to Tito and Scott. The second rules is a `<deny>` element that denies access to everyone. If an anonymous user visits, the `UrlAuthorizationModule` starts by asking, Is anonymous either Scott or Tito? The answer, obviously, is No, so it proceeds to the second rule. Is anonymous in the set of everybody? Since the answer here is Yes, the `<deny>` rule is put in effect and the visitor is redirected to the login page. Similarly, if Jisun is visiting, the `UrlAuthorizationModule` starts by asking, Is Jisun either Scott or Tito? Since she is not, the

`UrlAuthorizationModule` proceeds to the second question, Is Jisun in the set of everybody? She is, so she, too, is denied access. Finally, if Tito visits, the first question posed by the `UrlAuthorizationModule` is an affirmative answer, so Tito is granted access.

Since the `UrlAuthorizationModule` processes the authorization rules from the top down, stopping at any match, it is important to have the more specific rules come before the less specific ones. That is, to define authorization rules that forbid Jisun and anonymous users, but allow all other authenticated users, you would start with the most specific rule - the one impacting Jisun - and then proceed to the less specific rules - those allowing all other authenticated users, but denying all anonymous users. The following URL authorization rules implements this policy by first denying Jisun, and then denying any anonymous user. Any authenticated user other than Jisun will be granted access because neither of these `<deny>` statements will match.

```
<authorization>
 <deny users="Jisun" />
 <deny users="?" />
</authorization>
```

Step 2: Fixing the Workflow for Unauthorized, Authenticated Users

As we discussed earlier in this tutorial in the A Look at the URL Authorization Workflow section, anytime an unauthorized request transpires, the `UrlAuthorizationModule` aborts the request and returns an HTTP 401 Unauthorized status. This 401 status is modified by the `FormsAuthenticationModule` into a 302 Redirect status that sends the user to the login page. This workflow occurs on any unauthorized request, even if the user is authenticated.

Returning an authenticated user to the login page is likely to confuse them since they have already logged into the system. With a little bit of work we can improve this workflow by redirecting authenticated users who make unauthorized requests to a page that explains that they have attempted to access a restricted page.

Start by creating a new ASP.NET page in the web application's root folder named `UnauthorizedAccess.aspx`; don't forget to associate this page with the `Site.master` master page. After creating this page, remove the Content control that references the `LoginContent` ContentPlaceHolder so that the master page's default content will be displayed. Next, add a message that explains the situation, namely that the user attempted to access a protected resource. After adding such a message, the `UnauthorizedAccess.aspx` page's declarative markup should look similar to the following:

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" AutoEventWireup="true"
CodeFile="UnauthorizedAccess.aspx.cs" Inherits="UnauthorizedAccess"
Title="Untitled Page" %>

<asp:Content ID="Content1" ContentPlaceHolderID="MainContent"
Runat="Server">
 <h2>Unauthorized Access</h2>
 <p>
 You have attempted to access a page that you are not authorized to view.
 </p>
 <p>
 If you have any questions, please contact the site administrator.
 </p>
</asp:Content>
```

We now need to alter the workflow so that if an unauthorized request is performed by an authenticated user they are sent to the `UnauthorizedAccess.aspx` page instead of the login page. The logic that redirects unauthorized requests to the login page is buried within a private method of the `FormsAuthenticationModule` class, so we cannot customize this behavior. What we can do, however, is add our own logic to the login page

that redirects the user to `UnauthorizedAccess.aspx`, if needed.

When the `FormsAuthenticationModule` redirects an unauthorized visitor to the login page it appends the requested, unauthorized URL to the querystring with the name `ReturnUrl`. For example, if an unauthorized user attempted to visit `OnlyTito.aspx`, the `FormsAuthenticationModule` would redirect them to `Login.aspx?ReturnUrl=OnlyTito.aspx`. Therefore, if the login page is reached by an authenticated user with a querystring that includes the `ReturnUrl` parameter, then we know that this unauthenticated user just attempted to visit a page she is not authorized to view. In such a case, we want to redirect her to `UnauthorizedAccess.aspx`.

To accomplish this, add the following code to the login page's `Page_Load` event handler:

```
protected void Page_Load(object sender, EventArgs e)
{
    if (!Page.IsPostBack)
    {
        if (Request.IsAuthenticated && !string.IsNullOrEmpty(Request.QueryString["ReturnUrl"]))
        // This is an unauthorized, authenticated request...
        Response.Redirect("~/UnauthorizedAccess.aspx");
    }
}
```

The above code redirects authenticated, unauthorized users to the `UnauthorizedAccess.aspx` page. To see this logic in action, visit the site as an anonymous visitor and click on the Creating User Accounts link in the left column. This will take you to the `~/Membership/CreatingUserAccounts.aspx` page, which in Step 1 we configured to only permit access to Tito. Since anonymous users are prohibited, the `FormsAuthenticationModule` redirects us back to the login page.

At this point we are anonymous, so `Request.IsAuthenticated` returns `false` and we are not redirected to `UnauthorizedAccess.aspx`. Instead, the login page is displayed. Log in as a user other than Tito, such as Bruce. After entering the appropriate credentials, the login page redirects us back to `~/Membership/CreatingUserAccounts.aspx`. However, since this page is only accessible to Tito, we are unauthorized to view it and are promptly returned to the login page. This time, however, `Request.IsAuthenticated` returns `true` (and the `ReturnUrl` querystring parameter exists), so we are redirected to the `UnauthorizedAccess.aspx` page.

Figure 6: Authenticated, Unauthorized Users are Redirected to `UnauthorizedAccess.aspx` (Click to view full-size image)

This customized workflow presents a more sensible and straightforward user experience by short circuiting the

cycle depicted in Figure 2.

Step 3: Limiting Functionality Based on the Currently Logged In User

URL authorization makes it easy to specify coarse authorization rules. As we saw in Step 1, with URL authorization we can succinctly state what identities are permitted and which ones are denied from viewing a particular page or all pages in a folder. In certain scenarios, however, we may want to allow all users to visit a page, but limit the page's functionality based on the user visiting it.

Consider the case of an eCommerce website that allows authenticated visitors to review their products. When an anonymous user visits a product's page, they would see just the product information and would not be given the opportunity to leave a review. However, an authenticated user visiting the same page would see the reviewing interface. If the authenticated user had not yet reviewed this product, the interface would enable them to submit a review; otherwise it would show them their previously-submitted review. To take this scenario a step further, the product page might show additional information and offer extended features for those users that work for the eCommerce company. For example, the product page might list the inventory in stock and include options to edit the product's price and description when visited by an employee.

Such fine grain authorization rules can be implemented either declaratively or programmatically (or through some combination of the two). In the next section we will see how to implement fine grain authorization via the LoginView control. Following that, we will explore programmatic techniques. Before we can look at applying fine grain authorization rules, however, we first need to create a page whose functionality depends on the user visiting it.

Let's create a page that lists the files in a particular directory within a GridView. Along with listing each file's name, size, and other information, the GridView will include two columns of LinkButtons: one titled View and one titled Delete. If the View LinkButton is clicked, the contents of the selected file will be displayed; if the Delete LinkButton is clicked, the file will be deleted. Let's initially create this page such that its view and delete functionality is available to all users. In the Using the LoginView Control and Programmatically Limiting Functionality sections we will see how to enable or disable these features based on the user visiting the page.

> **NOTE**
>
> The ASP.NET page we are about to build uses a GridView control to display a list of files. Since this tutorial series focuses on forms authentication, authorization, user accounts, and roles, I do not want to spend too much time discussing the inner workings of the GridView control. While this tutorial provides specific step-by-step instructions for setting up this page, it does not delve into the details of why certain choices were made, or what effect particular properties have on the rendered output. For a thorough examination of the GridView control, consult my *Working with Data in ASP.NET 2.0* tutorial series.

Start by opening the `UserBasedAuthorization.aspx` file in the `Membership` folder and adding a GridView control to the page named `FilesGrid`. From the GridView's Smart Tag, click the Edit Columns link to launch the Fields dialog box. From here, uncheck the Auto-generate fields checkbox in the lower left corner. Next, add a Select button, a Delete button, and two BoundFields from the upper left corner (the Select and Delete buttons can be found under the CommandField type). Set the Select button's `SelectText` property to View and the first BoundField's `HeaderText` and `DataField` properties to Name. Set the second BoundField's `HeaderText` property to Size in Bytes, its `DataField` property to Length, its `DataFormatString` property to {0:N0} and its `HtmlEncode` property to False.

After configuring the GridView's columns, click OK to close the Fields dialog box. From the Properties window, set the GridView's `DataKeyNames` property to `FullName`. At this point the GridView's declarative markup should look like the following:

```
<asp:GridView ID="FilesGrid" DataKeyNames="FullName" runat="server" AutoGenerateColumns="False">
 <Columns>
 <asp:CommandField SelectText="View" ShowSelectButton="True"/>
 <asp:CommandField ShowDeleteButton="True" />
 <asp:BoundField DataField="Name" HeaderText="Name" />
 <asp:BoundField DataField="Length" DataFormatString="{0:N0}"
 HeaderText="Size in Bytes" HtmlEncode="False" />
 </Columns>
</asp:GridView>
```

With the GridView's markup created, we're ready to write the code that will retrieve the files in a particular directory and bind them to the GridView. Add the following code to the page's `Page_Load` event handler:

```
protected void Page_Load(object sender, EventArgs e)
{
    if (!Page.IsPostBack)
    {
        string appPath = Request.PhysicalApplicationPath;
        DirectoryInfo dirInfo = new DirectoryInfo(appPath);

        FileInfo[] files = dirInfo.GetFiles();

        FilesGrid.DataSource = files;
        FilesGrid.DataBind();
    }
}
```

The above code uses the `DirectoryInfo` class to obtain a list of the files in the application's root folder. The `GetFiles()` method returns all of the files in the directory as an array of `FileInfo` objects, which is then bound to the GridView. The `FileInfo` object has an assortment of properties, such as `Name`, `Length`, and `IsReadOnly`, among others. As you can see from its declarative markup, the GridView displays just the `Name` and `Length` properties.

NOTE

The `DirectoryInfo` and `FileInfo` classes are found in the `System.IO` namespace. Therefore, you will either need to preface these class names with their namespace names or have the namespace imported into the class file (via `using System.IO`).

Take a moment to visit this page through a browser. It will display the list of files residing in the application's root directory. Clicking any of the View or Delete LinkButtons will cause a postback, but no action will occur because we've yet to create the necessary event handlers.

Figure 7: The GridView Lists the Files in the Web Application's Root Directory (Click to view full-size image)

We need a means to display the contents of the selected file. Return to Visual Studio and add a TextBox named `FileContents` above the GridView. Set its `TextMode` property to `MultiLine` and its `Columns` and `Rows` properties to 95% and 10, respectively.

```
<asp:TextBox ID="FileContents" runat="server" Rows="10"
TextMode="MultiLine" Width="95%"></asp:TextBox>
```

Next, create an event handler for the GridView's `SelectedIndexChanged` event and add the following code:

```
protected void FilesGrid_SelectedIndexChanged(object sender, EventArgs e)
{
    // Open the file and display it
    string fullFileName = FilesGrid.SelectedValue.ToString();
    string contents = File.ReadAllText(fullFileName);
    FileContents.Text = contents;
}
```

This code uses the GridView's `SelectedValue` property to determine the full file name of the selected file. Internally, the `DataKeys` collection is referenced in order to obtain the `SelectedValue`, so it is imperative that you set the GridView's `DataKeyNames` property to Name, as described earlier in this step. The `File` class is used to read the selected file's contents into a string, which is then assigned to the `FileContents` TextBox's `Text` property, thereby displaying the contents of the selected file on the page.

Figure 8: The Selected File's Contents are Displayed in the TextBox (Click to view full-size image)

> **NOTE**
>
> If you view the contents of a file that contains HTML markup, and then attempt to view or delete a file, you will receive an `HttpRequestValidationException` error. This occurs because on postback the TextBox's contents are sent back to the web server. By default, ASP.NET raises an `HttpRequestValidationException` error whenever potentially dangerous postback content, such as HTML markup, is detected. To disable this error from occurring, turn off request validation for the page by adding `ValidateRequest="false"` to the `@Page` directive. For more information on the benefits of request validation as well as what precautions you should take when disabling it, read Request Validation - Preventing Script Attacks.

Finally, add an event handler with the following code for the GridView's `RowDeleting` event:

```
protected void FilesGrid_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
    string fullFileName = FilesGrid.DataKeys[e.RowIndex].Value.ToString();
    FileContents.Text = string.Format("You have opted to delete {0}.", fullFileName);

    // To actually delete the file, uncomment the following line
    // File.Delete(fullFileName);
}
```

The code simply displays the full name of the file to delete in the `FileContents` TextBox *without* actually deleting the file.

Figure 9: Clicking the Delete Button Does Not Actually Delete the File (Click to view full-size image)

In Step 1 we configured the URL authorization rules to prohibit anonymous users from viewing the pages in the `Membership` folder. In order to better exhibit fine grain authentication, let's allow anonymous users to visit the `UserBasedAuthorization.aspx` page, but with limited functionality. To open this page up to be accessed by all users, add the following `<location>` element to the `Web.config` file in the `Membership` folder:

```
<location path="UserBasedAuthorization.aspx">
 <system.web>
 <authorization>
 <allow users="*" />
 </authorization>
 </system.web>
</location>
```

After adding this `<location>` element, test the new URL authorization rules by logging out of the site. As an anonymous user you should be permitted to visit the `UserBasedAuthorization.aspx` page.

Currently, any authenticated or anonymous user can visit the `UserBasedAuthorization.aspx` page and view or delete files. Let's make it so that only authenticated users can view contents of a file and only Tito can delete a file. Such fine grain authorization rules can be applied declaratively, programmatically, or through a combination of both methods. Let's use the declarative approach to limit who can view the contents of a file; we'll use the programmatic approach to limit who can delete a file.

Using the LoginView Control

As we've seen in past tutorials, the LoginView control is useful for displaying different interfaces for authenticated and anonymous users, and offers an easy way to hide functionality that is not accessible to anonymous users. Since anonymous users cannot view or delete files, we only need to show the `FileContents` TextBox when the page is visited by an authenticated user. To achieve this, add a LoginView control to the page, name it `LoginViewForFileContentsTextBox`, and move the `FileContents` TextBox's declarative markup into the LoginView control's `LoggedInTemplate`.

```
<asp:LoginView ID=" LoginViewForFileContentsTextBox " runat="server">
 <LoggedInTemplate>
 <p>
 <asp:TextBox ID="FileContents" runat="server" Rows="10"
 TextMode="MultiLine" Width="95%"></asp:TextBox>
 </p>
 </LoggedInTemplate>
</asp:LoginView>
```

The Web controls in the LoginView's templates are no longer directly accessible from the code-behind class. For example, the `FilesGrid` GridView's `SelectedIndexChanged` and `RowDeleting` event handlers currently reference the `FileContents` TextBox control with code like:

```
FileContents.Text = text;
```

However, this code is no longer valid. By moving the `FileContents` TextBox into the `LoggedInTemplate` the TextBox cannot be directly accessed. Instead, we must use the `FindControl("controlId")` method to programmatically reference the control. Update the `FilesGrid` event handlers to reference the TextBox like so:

```
TextBox FileContentsTextBox = LoginViewForFileContentsTextBox.FindControl("FileContents") as TextBox;
FileContentsTextBox.Text = text;
```

After moving the TextBox to the LoginView's `LoggedInTemplate` and updating the page's code to reference the TextBox using the `FindControl("controlId")` pattern, visit the page as an anonymous user. As Figure 10 shows, the `FileContents` TextBox is not displayed. However, the View LinkButton is still displayed.

Figure 10: The LoginView Control Only Renders the `FileContents` TextBox for Authenticated Users (Click to view full-size image)

One way to hide the View button for anonymous users is to convert the GridView field into a TemplateField. This will generate a template that contains the declarative markup for the View LinkButton. We can then add a LoginView control to the TemplateField and place the LinkButton within the LoginView's `LoggedInTemplate`, thereby hiding the View button from anonymous visitors. To accomplish this, click on the Edit Columns link from the GridView's Smart Tag to launch the Fields dialog box. Next, select the Select button from the list in the lower left corner and then click the Convert this field to a TemplateField link. Doing so will modify the field's declarative markup from:

```
<asp:CommandField SelectText="View" ShowSelectButton="True"/>
```

To:

```
<asp:TemplateField ShowHeader="False">
 <ItemTemplate>
 <asp:LinkButton ID="LinkButton1" runat="server" CausesValidation="False"
 CommandName="Select" Text="View"></asp:LinkButton>
 </ItemTemplate>
</asp:TemplateField>
```

At this point, we can add a LoginView to the TemplateField. The following markup displays the View LinkButton only for authenticated users.

```
<asp:TemplateField ShowHeader="False">
 <ItemTemplate>
 <asp:LoginView ID="LoginView1" runat="server">
 <LoggedInTemplate>
 <asp:LinkButton ID="LinkButton1" runat="server" CausesValidation="False"
 CommandName="Select" Text="View"></asp:LinkButton>
 </LoggedInTemplate>
 </asp:LoginView>
 </ItemTemplate>
</asp:TemplateField>
```

As Figure 11 shows, the end result is not that pretty as the View column is still displayed even though the View LinkButtons within the column are hidden. We will look at how to hide the entire GridView column (and not just the LinkButton) in the next section.

Figure 11: The LoginView Control Hides the View LinkButtons for Anonymous Visitors (Click to view full-size image)

Programmatically Limiting Functionality

In some circumstances, declarative techniques are insufficient for limiting functionality to a page. For example, the availability of certain page functionality may be dependent on criteria beyond whether the user visiting the page is anonymous or authenticated. In such cases, the various user interface elements can be displayed or hidden through programmatic means.

In order to limit the functionality programmatically, we need to perform two tasks:

1. Determine whether the user visiting the page can access the functionality, and
2. Programmatically modify the user interface based on whether the user has access to the functionality in question.

To demonstrate the application of these two tasks, let's only allow Tito to delete files from the GridView. Our first task, then, is to determine whether it is Tito visiting the page. Once that has been determined, we need to hide (or show) the GridView's Delete column. The GridView's columns are accessible through its `Columns` property; a column is only rendered if its `Visible` property is set to `true` (the default).

Add the following code to the `Page_Load` event handler prior to binding the data to the GridView:

```
// Is this Tito visiting the page?
string userName = User.Identity.Name;
if (string.Compare(userName, "Tito", true) == 0)
    // This is Tito, SHOW the Delete column
    FilesGrid.Columns[1].Visible = true;
else
    // This is NOT Tito, HIDE the Delete column
    FilesGrid.Columns[1].Visible = false;
```

As we discussed in the *An Overview of Forms Authentication* tutorial, `User.Identity.Name` returns the identity's name. This corresponds to the username entered in the Login control. If it is Tito visiting the page, the GridView's

second column's `Visible` property is set to `true`; otherwise, it is set to `false`. The net result is that when someone other than Tito visits the page, either another authenticated user or an anonymous user, the Delete column is not rendered (see Figure 12); however, when Tito visits the page, the Delete column is present (see Figure 13).

Figure 12: The Delete Column is Not Rendered When Visited By Someone Other Than Tito (Such as Bruce) (Click to view full-size image)

Figure 13: The Delete Column is Rendered for Tito (Click to view full-size image)

Step 4: Applying Authorization Rules to Classes and Methods

In Step 3 we disallowed anonymous users from viewing a file's contents and prohibited all users but Tito from deleting files. This was accomplished by hiding the associated user interface elements for unauthorized visitors

through declarative and programmatic techniques. For our simple example, properly hiding the user interface elements was straightforward, but what about more complex sites where there may be many different ways to perform the same functionality? In limiting that functionality to unauthorized users, what happens if we forget to hide or disable all of the applicable user interface elements?

An easy way to ensure that a particular piece of functionality cannot be accessed by an unauthorized user is to decorate that class or method with the `PrincipalPermission` attribute. When the .NET runtime uses a class or executes one of its methods, it checks to ensure that the current security context has permission to use the class or execute the method. The `PrincipalPermission` attribute provides a mechanism through which we can define these rules.

Let's demonstrate using the `PrincipalPermission` attribute on the GridView's `SelectedIndexChanged` and `RowDeleting` event handlers to prohibit execution by anonymous users and users other than Tito, respectively. All we need to do is add the appropriate attribute atop each function definition:

```
[PrincipalPermission(SecurityAction.Demand, Authenticated=true)]
protected void FilesGrid_SelectedIndexChanged(object sender, EventArgs e)
{
    ...
}

[PrincipalPermission(SecurityAction.Demand, Name="Tito")]
protected void FilesGrid_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
    ...
}
```

The attribute for the `SelectedIndexChanged` event handler dictates that only authenticated users can execute the event handler, where as the attribute on the `RowDeleting` event handler limits the execution to Tito.

If, somehow, a user other than Tito attempts to execute the `RowDeleting` event handler or a non-authenticated user attempts to execute the `SelectedIndexChanged` event handler, the .NET runtime will raise a `SecurityException`.

Figure 14: If the Security Context is not Authorized to Execute the Method, a `SecurityException` is Thrown (Click to view full-size image)

> **NOTE**
> To allow multiple security contexts to access a class or method, decorate the class or method with a `PrincipalPermission` attribute for each security context. That is, to allow both Tito and Bruce to execute the `RowDeleting` event handler, add *two* `PrincipalPermission` attributes:

```
[PrincipalPermission(SecurityAction.Demand, Name="Tito")]

[PrincipalPermission(SecurityAction.Demand, Name="Bruce")]
```

In addition to ASP.NET pages, many applications also have an architecture that includes various layers, such as Business Logic and Data Access Layers. These layers are typically implemented as Class Libraries and offer classes and methods for performing business logic- and data-related functionality. The `PrincipalPermission` attribute is useful for applying authorization rules to these layers.

For more information on using the `PrincipalPermission` attribute to define authorization rules on classes and methods, refer to Scott Guthrie's blog entry Adding Authorization Rules to Business and Data Layers Using `PrincipalPermissionAttributes`.

Summary

In this tutorial we looked at how to apply user-based authorization rules. We started with a look at ASP.NET's URL authorization framework. On each request, the ASP.NET engine's `UrlAuthorizationModule` inspects the URL authorization rules defined in the application's configuration to determine whether the identity is authorized to access the requested resource. In short, URL authorization makes it easy to specify authorization rules for a specific page or for all pages in a particular directory.

The URL authorization framework applies authorization rules on a page-by-page basis. With URL authorization, either the requesting identity is authorized to access a particular resource or not. Many scenarios, however, call for more fine grain authorization rules. Rather than defining who is permitted to access a page, we may need to let everyone access a page, but to show different data or offer different functionality depending on the user visiting the page. Page-level authorization usually involves hiding specific user interface elements in order to prevent unauthorized users from accessing prohibited functionality. Additionally, it is possible to use attributes to restrict access to classes and execution of its methods for certain users.

Happy Programming!

> In this tutorial we will answer this question by building a very rudimentary guestbook application. In doing so, we will look at different options for modeling user information in a database, and then see how to associate this data with the user accounts created by the Membership framework.

Introduction

ASP.NET's Membership framework offers a flexible interface for managing users. The Membership API includes methods for validating credentials, retrieving information about the currently logged on user, creating a new user account, and deleting a user account, among others. Each user account in the Membership framework contains only the properties needed for validating credentials and performing essential user account-related tasks. This is evidenced by the methods and properties of the `MembershipUser` class, which models a user account in the Membership framework. This class has properties like `UserName`, `Email`, and `IsLockedOut`, and methods like `GetPassword` and `UnlockUser`.

Oftentimes, applications need to store additional user information not included in the Membership framework. For example, an online retailer might need to let each user store her shipping and billing addresses, payment information, delivery preferences, and contact phone number. Furthermore, each order in the system is associated with a particular user account.

The `MembershipUser` class does not include properties like `PhoneNumber` or `DeliveryPreferences` or `PastOrders`. So how do we track the user information needed by the application and have it integrate with the Membership framework? In this tutorial we will answer this question by building a very rudimentary guestbook application. In doing so, we will look at different options for modeling user information in a database, and then see how to associate this data with the user accounts created by the Membership framework. Let's get started!

Step 1: Creating the Guestbook Application's Data Model

There are a variety of techniques that can be employed to capture user information in a database and associate it with the user accounts created by the Membership framework. In order to illustrate these techniques, we will need to augment the tutorial web application so that it captures some sort of user-related data. (Currently, the application's data model contains only the application services tables needed by the `SqlMembershipProvider`.)

Let's create a very simple guestbook application where an authenticated user can leave a comment. In addition to storing guestbook comments, let's allow each user to store his home town, homepage, and signature. If provided, the user's home town, homepage, and signature will appear on each message he has left in the guestbook.

Adding the `GuestbookComments` Table

In order to capture the guestbook comments, we need to create a database table named `GuestbookComments` that has columns like `CommentId`, `Subject`, `Body`, and `CommentDate`. We also need to have each record in the `GuestbookComments` table reference the user who left the comment.

To add this table to our database, go to the Database Explorer in Visual Studio and drill down into the `SecurityTutorials` database. Right-click on the Tables folder and choose Add New Table. This brings up an interface that allows us to define the columns for the new table.

Figure 1: Add a New Table to the `SecurityTutorials` Database (Click to view full-size image)

Next, define the `GuestbookComments`'s columns. Start by adding a column named `CommentId` of type `uniqueidentifier`. This column will uniquely identify each comment in the guestbook, so disallow `NULL`s and mark it as the table's primary key. Rather than providing a value for the `CommentId` field on each `INSERT`, we can indicate that a new `uniqueidentifier` value should be automatically generated for this field on `INSERT` by setting the column's default value to `NEWID()`. After adding this first field, marking it as the primary key, and settings its default value, your screen should look similar to the screen shot shown in Figure 2.

Figure 2: Add a Primary Column Named `CommentId` (Click to view full-size image)

Next, add a column named `Subject` of type `nvarchar(50)` and a column named `Body` of type `nvarchar(MAX)`, disallowing `NULL`s in both columns. Following that, add a column named `CommentDate` of type `datetime`. Disallow `NULL`s and set the `CommentDate` column's default value to `getdate()`.

All that remains is to add a column that associates a user account with each guestbook comment. One option would be to add a column named `UserName` of type `nvarchar(256)`. This is a suitable choice when using a Membership provider other than the `SqlMembershipProvider`. But when using the `SqlMembershipProvider`, as we

are in this tutorial series, the `UserName` column in the `aspnet_Users` table is not guaranteed to be unique. The `aspnet_Users` table's primary key is `UserId` and is of type `uniqueidentifier`. Therefore, the `GuestbookComments` table needs a column named `UserId` of type `uniqueidentifier` (disallowing `NULL` values). Go ahead and add this column.

> **NOTE**
>
> As we discussed in the *Creating the Membership Schema in SQL Server* tutorial, the Membership framework is designed to enable multiple web applications with different user accounts to share the same user store. It does this by partitioning user accounts into different applications. And while each username is guaranteed to be unique within an application, the same username may be used in different applications using the same user store. There is a composite `UNIQUE` constraint in the `aspnet_Users` table on the `UserName` and `ApplicationId` fields, but not one on just the `UserName` field. Consequently, it is possible for the aspnet_Users table to have two (or more) records with the same `UserName` value. There is, however, a `UNIQUE` constraint on the `aspnet_Users` table's `UserId` field (since it is the primary key). A `UNIQUE` constraint is important because without it we cannot establish a foreign key constraint between the `GuestbookComments` and `aspnet_Users` tables.

After adding the `UserId` column, save the table by clicking on the Save icon in the Toolbar. Name the new table `GuestbookComments`.

We have one last issue to attend to with the `GuestbookComments` table: we need to create a foreign key constraint between the `GuestbookComments.UserId` column and the `aspnet_Users.UserId` column. To achieve this, click the Relationship icon in the Toolbar to launch the Foreign Key Relationships dialog box. (Alternatively, you can launch this dialog box by going to the Table Designer menu and choosing Relationships.)

Click the Add button in the lower left corner of the Foreign Key Relationships dialog box. This will add a new foreign key constraint, although we still need to define the tables that participate in the relationship.

Figure 3: Use the Foreign Key Relationships Dialog Box to Manage a Table's Foreign Key Constraints (Click to view full-size image)

Next, click the ellipses icon in the "Table and Columns Specifications" row on the right. This will launch the Tables and Columns dialog box, from which we can specify the primary key table and column and the foreign key column from the `GuestbookComments` table. In particular, select `aspnet_Users` and `UserId` as the primary key table and column, and `UserId` from the `GuestbookComments` table as the foreign key column (see Figure 4). After defining the primary and foreign key tables and columns, click OK to return to the Foreign Key Relationships dialog box.

Figure 4: Establish a Foreign Key Constraint Between the `aspnet_Users` and `GuesbookComments` Tables (Click to view full-size image)

At this point the foreign key constraint has been established. The presence of this constraint ensures relational integrity between the two tables by guaranteeing that there will never be a guestbook entry referring to a non-existent user account. By default, a foreign key constraint will disallow a parent record to be deleted if there are corresponding child records. That is, if a user makes one or more guestbook comments, and then we attempt to delete that user account, the delete will fail unless his guestbook comments are deleted first.

Foreign key constraints can be configured to automatically delete the associated child records when a parent record is deleted. In other words, we can setup this foreign key constraint so that a user's guestbook entries are automatically deleted when her user account is deleted. To accomplish this, expand the "INSERT And UPDATE Specification" section and set the "Delete Rule" property to Cascade.

Figure 5: Configure the Foreign Key Constraint to Cascade Deletes (Click to view full-size image)

To save the foreign key constraint, click the Close button to exit out of the Foreign Key Relationships. Then click the Save icon in the Toolbar to save the table and the this relationship.

Storing the User's Home Town, Homepage, and Signature

The `GuestbookComments` table illustrates how to store information that shares a one-to-many relationship with user accounts. Since each user account may have an arbitrary number of associated comments, this relationship is modeled by creating a table to hold the set of comments that includes a column that links back each comment to a particular user. When using the `SqlMembershipProvider`, this link is best established by creating a column

named `UserId` of type `uniqueidentifier` and a foreign key constraint between this column and `aspnet_Users.UserId`.

We now need to associate three columns with each user account to store the user's home town, homepage, and signature, which will appear in his guestbook comments. There are number of different ways to accomplish this:

- **Add new columns to the `aspnet_Users` or `aspnet_Membership` tables.** I would not recommend this approach because it modifies the schema used by the `SqlMembershipProvider`. This decision may come back to haunt you down the road. For example, what if a future version of ASP.NET uses a different `SqlMembershipProvider` schema. Microsoft may include a tool to migrate the ASP.NET 2.0 `SqlMembershipProvider` data to the new schema, but if you have modified the ASP.NET 2.0 `SqlMembershipProvider` schema, such a conversion may not be possible.

- **Use ASP.NET's Profile framework, defining a profile property for the home town, homepage, and signature.** ASP.NET includes a Profile framework that is designed to store additional user-specific data. Like the Membership framework, the Profile framework is built atop the provider model. The .NET Framework ships with a `SqlProfileProvider` sthat stores profile data in a SQL Server database. In fact, our database already has the table used by the `SqlProfileProvider` (`aspnet_Profile`), as it was added when we added the application services back in the *Creating the Membership Schema in SQL Server* tutorial. The main benefit of the Profile framework is that it allows for developers to define the profile properties in `Web.config` – no code needs to be written to serialize the profile data to and from the underlying data store. In short, it is incredibly easy to define a set of profile properties and to work with them in code. However, the Profile system leaves a lot to be desired when it comes to versioning, so if you have an application where you expect new user-specific properties to be added at a later time, or existing ones to be removed or modified, then the Profile framework may not be the best option. Moreover, the `SqlProfileProvider` stores the profile properties in a highly denormalized fashion, making it next to impossible to run queries directly against the profile data (such as, how many users have a home town of New York).
  For more information on the Profile framework, consult the "Further Readings" section at the end of this tutorial.

- **Add these three columns to a new table in the database and establish a one-to-one relationship between this table and `aspnet_Users`.** This approach involves a bit more work than with the Profile framework, but offers maximum flexibility in how the additional user properties are modeled in the database. This is the option we will use in this tutorial.

We will create a new table called `UserProfiles` to save the home town, homepage, and signature for each user. Right-click on the Tables folder in the Database Explorer window and choose to create a new table. Name the first column `UserId` and set its type to `uniqueidentifier`. Disallow `NULL` values and mark the column as a primary key. Next, add columns named: `HomeTown` of type `nvarchar(50)`; `HomepageUrl` of type `nvarchar(100)`; and Signature of type `nvarchar(500)`. Each of these three columns can accept a `NULL` value.

Figure 6: Create the `UserProfiles` Table (Click to view full-size image)

Save the table and name it `UserProfiles`. Lastly, establish a foreign key constraint between the `UserProfiles` table's `UserId` field and the `aspnet_Users.UserId` field. As we did with the foreign key constraint between the `GuestbookComments` and `aspnet_Users` tables, have this constraint cascade deletes. Since the `UserId` field in `UserProfiles` is the primary key, this ensures that there will be no more than one record in the `UserProfiles` table for each user account. This type of relationship is referred to as one-to-one.

Now that we have the data model created, we are ready to use it. In Steps 2 and 3 we will look at how the currently logged on user can view and edit their home town, homepage, and signature information. In Step 4 we will create the interface for authenticated users to submit new comments to the guestbook and view the existing ones.

Step 2: Displaying the User's Home Town, Homepage, and Signature

There are a variety of ways to allow the currently logged on user to view and edit his home town, homepage, and signature information. We could manually create the user interface with TextBox and Label controls or we could use one of the data Web controls, such as the DetailsView control. To perform the database `SELECT` and `UPDATE` statements we could write ADO.NET code in our page's code-behind class or, alternatively, employ a declarative approach with the SqlDataSource. Ideally our application would contain a tiered architecture, which we could either invoke programmatically from the page's code-behind class or declaratively via the ObjectDataSource control.

Since this tutorial series focuses on forms authentication, authorization, user accounts, and roles, there will not be a thorough discussion of these different data access options or why a tiered architecture is preferred over executing SQL statements directly from the ASP.NET page. I am going to walk through using a DetailsView and SqlDataSource – the quickest and easiest option – but the concepts discussed can certainly be applied to alternative Web controls and data access logic. For more information on working with data in ASP.NET, refer to my *Working with Data in ASP.NET 2.0* tutorial series.

Open the `AdditionalUserInfo.aspx` page in the `Membership` folder and add a DetailsView control to the page,

setting its `ID` property to `UserProfile` and clearing out its `Width` and `Height` properties. Expand the DetailsView's Smart Tag and choose to bind it to a new data source control. This will launch the DataSource Configuration Wizard (see Figure 7). The first step asks you to specify the data source type. Since we are going to connect directly to the `SecurityTutorials` database, choose the Database icon, specifying the `ID` as `UserProfileDataSource`.

Figure 7: Add a New SqlDataSource Control Named `UserProfileDataSource` (Click to view full-size image)

The next screen prompts for the database to use. We have already defined a connection string in `Web.config` for the `SecurityTutorials` database. This connection string name – `SecurityTutorialsConnectionString` – should be in the drop-down list. Select this option and click Next.

Figure 8: Choose `SecurityTutorialsConnectionString` from the Drop-Down List (Click to view full-size image)

The subsequent screen asks us to specify the table and columns to query. Choose the `UserProfiles` table from the drop-down list and check all of the columns.

Figure 9: Bring Back All of the Columns from the `UserProfiles` Table (Click to view full-size image)

The current query in Figure 9 returns *all* of the records in `UserProfiles`, but we are only interested in the currently logged on user's record. To add a `WHERE` clause, click the `WHERE` button to bring up the Add `WHERE` Clause dialog box (see Figure 10). Here you can select the column to filter on, the operator, and the source of the filter parameter. Select `UserId` as the column and "=" as the Operator.

Unfortunately there is no built-in parameter source to return the currently logged on user's `UserId` value. We will need to grab this value programmatically. Therefore, set the Source drop-down list to "None," click the Add button to add the parameter, and then click OK.

Figure 10: Add a Filter Parameter on the `UserId` Column (Click to view full-size image)

After clicking OK you will be returned to the screen shown in Figure 9. This time, however, the SQL query at the bottom of the screen should include a `WHERE` clause. Click Next to move on to the "Test Query" screen. Here you can run the query and see the results. Click Finish to complete the wizard.

Upon completing the DataSource Configuration Wizard, Visual Studio creates the SqlDataSource control based on the settings specified in the wizard. Moreover, it manually adds BoundFields to the DetailsView for each

column returned by the SqlDataSource's `SelectCommand`. There's no need to show the `UserId` field in the DetailsView, since the user does not need to know this value. You can remove this field directly from the DetailsView control's declarative markup or by clicking the "Edit Fields" link from its Smart Tag.

At this point your page's declarative markup should look similar to the following:

```
<asp:DetailsView ID="UserProfile" runat="server"
     AutoGenerateRows="False" DataKeyNames="UserId"
     DataSourceID="UserProfileDataSource">
     <Fields>
          <asp:BoundField DataField="HomeTown" HeaderText="HomeTown"
               SortExpression="HomeTown" />
          <asp:BoundField DataField="HomepageUrl" HeaderText="HomepageUrl"
               SortExpression="HomepageUrl" />
          <asp:BoundField DataField="Signature" HeaderText="Signature"
               SortExpression="Signature" />
     </Fields>
</asp:DetailsView>
<asp:SqlDataSource ID="UserProfileDataSource" runat="server"
          ConnectionString="<%$ ConnectionStrings:SecurityTutorialsConnectionString %>"
          SelectCommand="SELECT [UserId], [HomeTown], [HomepageUrl], [Signature] FROM
          [UserProfiles] WHERE ([UserId] = @UserId)">
     <SelectParameters>
          <asp:Parameter Name="UserId" Type="Object" />
     </SelectParameters>
</asp:SqlDataSource>
```

We need to programmatically set the SqlDataSource control's `UserId` parameter to the currently logged in user's `UserId` before the data is selected. This can be accomplished by creating an event handler for the SqlDataSource's `Selecting` event and adding the following code there:

```
protected void UserProfileDataSource_Selecting(object sender,
          SqlDataSourceSelectingEventArgs e)
{
     // Get a reference to the currently logged on user
     MembershipUser currentUser = Membership.GetUser();

     // Determine the currently logged on user's UserId value
     Guid currentUserId = (Guid)currentUser.ProviderUserKey;

     // Assign the currently logged on user's UserId to the @UserId parameter
     e.Command.Parameters["@UserId"].Value = currentUserId;
}
```

The above code starts by obtaining a reference to the currently logged on user by calling the `Membership` class's `GetUser` method. This returns a `MembershipUser` object, whose `ProviderUserKey` property contains the `UserId`. The `UserId` value is then assigned to the SqlDataSource's `@UserId` parameter.

NOTE

The `Membership.GetUser()` method returns information about the currently logged on user. If an anonymous user is visiting the page, it will return a value of `null`. In such a case, this will lead to a `NullReferenceException` on the following line of code when attempting to read the `ProviderUserKey` property. Of course, we don't have to worry about `Membership.GetUser()` returning a `null` value in the `AdditionalUserInfo.aspx` page because we configured URL authorization in a previous tutorial so that only authenticated users could access the ASP.NET resources in this folder. If you need to access information about the currently logged on user in a page where anonymous access is permitted, make sure to check that a non-`null MembershipUser` object is returned from the `GetUser()` method before referencing its properties.

If you visit the `AdditionalUserInfo.aspx` page through a browser you will see a blank page because we have yet to add any rows to the `UserProfiles` table. In Step 6 we will look at how to customize the CreateUserWizard control to automatically add a new row to the `UserProfiles` table when a new user account is created. For now, however, we will need to manually create a record in the table.

Navigate to the Database Explorer in Visual Studio and expand the Tables folder. Right-click on the `aspnet_Users` table and choose "Show Table Data" to see the records in the table; do the same thing for the `UserProfiles` table. Figure 11 shows these results when tiled vertically. In my database there are currently `aspnet_Users` records for Bruce, Fred, and Tito, but no records in the `UserProfiles` table.

Figure 11: The Contents of the `aspnet_Users` and `UserProfiles` Tables are Displayed (Click to view full-size image)

Add a new record to the `UserProfiles` table by manually typing in values for the `HomeTown`, `HomepageUrl`, and `Signature` fields. The easiest way to get a valid `UserId` value in the new `UserProfiles` record is to select the `UserId` field from a particular user account in the `aspnet_Users` table and copy and paste it into the `UserId` field in `UserProfiles`. Figure 12 shows the `UserProfiles` table after a new record has been added for Bruce.

Figure 12: A Record was Added to `UserProfiles` for Bruce (Click to view full-size image)

Return to the `AdditionalUserInfo.aspx` page, logged in as Bruce. As Figure 13 shows, Bruce's settings are displayed.

Figure 13: The Currently Visiting User is Shown His Settings (Click to view full-size image)

> **NOTE**
>
> Go ahead and manually add records in the `UserProfiles` table for each Membership user. In Step 6 we will look at how to customize the CreateUserWizard control to automatically add a new row to the `UserProfiles` table when a new user account is created.

Step 3: Allowing the User to Edit His Home Town, Homepage, and Signature

At this point the currently logged in user can view their home town, homepage, and signature setting, but they cannot yet modify them. Let's update the DetailsView control so that the data can be edited.

The first thing we need to do is add an `UpdateCommand` for the SqlDataSource, specifying the `UPDATE` statement to execute and its corresponding parameters. Select the SqlDataSource and, from the Properties window, click on the ellipses next to the UpdateQuery property to bring up the Command and Parameter Editor dialog box. Enter the following `UPDATE` statement into the textbox:

```
UPDATE UserProfiles SET
     HomeTown = @HomeTown,
     HomepageUrl = @HomepageUrl,
     Signature = @Signature
WHERE UserId = @UserId
```

Next, click the "Refresh Parameters" button, which will create a parameter in the SqlDataSource control's `UpdateParameters` collection for each of the parameters in the `UPDATE` statement. Leave the source for all of the parameters set to None and click the OK button to complete the dialog box.

Figure 14: Specify the SqlDataSource's `UpdateCommand` and `UpdateParameters` (Click to view full-size image)

Due to the additions we made to the SqlDataSource control, the DetailsView control can now support editing. From the DetailsView's Smart Tag, check the "Enable Editing" checkbox. This adds a CommandField to the control's `Fields` collection with its `ShowEditButton` property set to True. This renders an Edit button when the DetailsView is displayed in read-only mode and Update and Cancel buttons when displayed in edit mode. Rather than requiring the user to click Edit, though, we can have the DetailsView render in an "always editable" state by setting the DetailsView control's `DefaultMode` property to `Edit`.

With these changes, your DetailsView control's declarative markup should look similar to the following:

```
<asp:DetailsView ID="UserProfile" runat="server"
          AutoGenerateRows="False" DataKeyNames="UserId"
          DataSourceID="UserProfileDataSource" DefaultMode="Edit">
     <Fields>
          <asp:BoundField DataField="HomeTown" HeaderText="HomeTown"
               SortExpression="HomeTown" />
          <asp:BoundField DataField="HomepageUrl" HeaderText="HomepageUrl"
               SortExpression="HomepageUrl" />
          <asp:BoundField DataField="Signature" HeaderText="Signature"
               SortExpression="Signature" />
          <asp:CommandField ShowEditButton="True" />
     </Fields>
</asp:DetailsView>
```

Note the addition of the CommandField and the `DefaultMode` property.

Go ahead and test this page through a browser. When visiting with a user that has a corresponding record in `UserProfiles`, the user's settings are displayed in an editable interface.

Figure 15: The DetailsView Renders an Editable Interface (Click to view full-size image)

Try changing the values and clicking the Update button. It appears as if nothing happens. There is a postback and the values are saved to the database, but there's no visual feedback that the save occurred.

To remedy this, return to Visual Studio and add a Label control above the DetailsView. Set its `ID` to `SettingsUpdatedMessage`, its `Text` property to "Your settings have been updated," and its `Visible` and `EnableViewState` properties to `false`.

```
<asp:Label ID="SettingsUpdatedMessage" runat="server"
     Text="Your settings have been updated."
     EnableViewState="false"
     Visible="false"></asp:Label>
```

We need to display the `SettingsUpdatedMessage` Label whenever the DetailsView is updated. To accomplish this, create an event handler for the DetailsView's `ItemUpdated` event and add the following code:

```
protected void UserProfile_ItemUpdated(object sender, DetailsViewUpdatedEventArgs e)
{
     SettingsUpdatedMessage.Visible = true;
}
```

Return to the `AdditionalUserInfo.aspx` page through a browser and update the data. This time, a helpful status message is displayed.

Figure 16: A Short Message is Displayed When the Settings are Updated (Click to view full-size image)

> **NOTE**
>
> The DetailsView control's editing interface leaves a lot to be desired. It uses standard-sized textboxes, but the Signature field should probably be a multi-line textbox. A RegularExpressionValidator should be used to ensure that the homepage URL, if entered, starts with "http://" or "https://". Moreover, since the DetailsView control has its `DefaultMode` property set to `Edit`, the Cancel button does not do anything. It should either be removed or, when clicked, redirect the user to some other page (such as `~/Default.aspx`). I leave these enhancements as an exercise for the reader.

Adding a Link to the `AdditionalUserInfo.aspx` Page in the Master Page

Currently, the website does not provide any links to the `AdditionalUserInfo.aspx` page. The only way to reach it is to enter the page's URL directly into the browser's Address bar. Let's add a link to this page in the `Site.master` master page.

Recall that the master page contains a LoginView Web control in its `LoginContent` ContentPlaceHolder that displays different markup for authenticated and anonymous visitors. Update the LoginView control's `LoggedInTemplate` to include a link to the `AdditionalUserInfo.aspx` page. After making these changes the LoginView control's declarative markup should look similar to the following:

```
<asp:LoginView ID="LoginView1" runat="server">
     <LoggedInTemplate>
          Welcome back,
          <asp:LoginName ID="LoginName1" runat="server" />.
          <br />
          <asp:HyperLink ID="lnkUpdateSettings" runat="server"
               NavigateUrl="~/Membership/AdditionalUserInfo.aspx">
               Update Your Settings</asp:HyperLink>
     </LoggedInTemplate>
     <AnonymousTemplate>
          Hello, stranger.
     </AnonymousTemplate>
</asp:LoginView>
```

Note the addition of the `lnkUpdateSettings` HyperLink control to the `LoggedInTemplate`. With this link in place, authenticated users can quickly jump to the page to view and modify their home town, homepage, and signature settings.

Step 4: Adding New Guestbook Comments

The `Guestbook.aspx` page is where authenticated users can view the guestbook and leave a comment. Let's start with creating the interface to add new guestbook comments.

Open the `Guestbook.aspx` page in Visual Studio and construct a user interface consisting of two TextBox controls, one for the new comment's subject and one for its body. Set the first TextBox control's `ID` property to `Subject` and its `Columns` property to 40; set second's `ID` to `Body`, its `TextMode` to `MultiLine`, and its `Width` and `Rows` properties to "95%" and 8, respectively. To complete the user interface, add a Button Web control named `PostCommentButton` and set its `Text` property to "Post Your Comment".

Since each guestbook comment requires a subject and body, add a RequiredFieldValidator for each of the TextBoxes. Set the `ValidationGroup` property of these controls to "EnterComment"; likewise, set the `PostCommentButton` control's `ValidationGroup` property to "EnterComment". For more information on ASP.NET's validation controls, check out Form Validation in ASP.NET, Dissecting the Validation Controls in ASP.NET 2.0, and the Validation Server Controls Tutorial on W3Schools.

After crafting the user interface your page's declarative markup should look something like the following:

```
<h3>Leave a Comment</h3>
<p>
     <b>Subject:</b>
     <asp:RequiredFieldValidator ID="SubjectReqValidator" runat="server"
          ErrorMessage="You must provide a value for Subject"
          ControlToValidate="Subject" ValidationGroup="EnterComment">
     </asp:RequiredFieldValidator><br/>
     <asp:TextBox ID="Subject" Columns="40" runat="server"></asp:TextBox>
</p>
<p>
     <b>Body:</b>
     <asp:RequiredFieldValidator ID="BodyReqValidator" runat="server"
          ControlToValidate="Body"
          ErrorMessage="You must provide a value for Body" ValidationGroup="EnterComment">
     </asp:RequiredFieldValidator><br/>
     <asp:TextBox ID="Body" TextMode="MultiLine" Width="95%"
          Rows="8" runat="server"></asp:TextBox>
</p>
<p>
     <asp:Button ID="PostCommentButton" runat="server"
          Text="Post Your Comment"
          ValidationGroup="EnterComment" />
</p>
```

With the user interface complete, our next task is to insert a new record into the `GuestbookComments` table when the `PostCommentButton` is clicked. This can be accomplished in a number of ways: we can write ADO.NET code in the Button's `Click` event handler; we can add a SqlDataSource control to the page, configure its `InsertCommand`, and then call its `Insert` method from the `Click` event handler; or we could build a middle tier that was responsible for inserting new guestbook comments, and invoke this functionality from the `Click` event handler. Since we looked at using a SqlDataSource in Step 3, let's use ADO.NET code here.

> **NOTE**
>
> The ADO.NET classes used to programmatically access data from a Microsoft SQL Server database are located in the `System.Data.SqlClient` namespace. You may need to import this namespace into your page's code-behind class (i.e., `using System.Data.SqlClient;`).

Create an event handler for the `PostCommentButton`'s `Click` event and add the following code:

```
protected void PostCommentButton_Click(object sender, EventArgs e)
{
     if (!Page.IsValid)
          return;

     // Determine the currently logged on user's UserId
     MembershipUser currentUser = Membership.GetUser();
     Guid currentUserId = (Guid)currentUser.ProviderUserKey;

     // Insert a new record into GuestbookComments
     string connectionString =
          ConfigurationManager.ConnectionStrings["SecurityTutorialsConnectionString"].ConnectionString;
     string insertSql = "INSERT INTO GuestbookComments(Subject, Body, UserId) VALUES(@Subject,
               @Body, @UserId)";

     using (SqlConnection myConnection = new SqlConnection(connectionString))
     {
          myConnection.Open();
          SqlCommand myCommand = new SqlCommand(insertSql, myConnection);
          myCommand.Parameters.AddWithValue("@Subject", Subject.Text.Trim());
          myCommand.Parameters.AddWithValue("@Body", Body.Text.Trim());
          myCommand.Parameters.AddWithValue("@UserId", currentUserId);
          myCommand.ExecuteNonQuery();
          myConnection.Close();
     }

     // "Reset" the Subject and Body TextBoxes
     Subject.Text = string.Empty;
     Body.Text = string.Empty;
}
```

The `Click` event handler starts by checking that the user-supplied data is valid. If it is not, the event handler exits before inserting a record. Assuming the supplied data is valid, the currently logged on user's `UserId` value is retrieved and stored in the `currentUserId` local variable. This value is needed because we must supply a `UserId` value when inserting a record into `GuestbookComments`.

Following that, the connection string for the `SecurityTutorials` database is retrieved from `Web.config` and the `INSERT` SQL statement is specified. A `SqlConnection` object is then created and opened. Next, a `SqlCommand` object is constructed and the values for the parameters used in the `INSERT` query are assigned. The `INSERT` statement is then executed and the connection closed. At the end of the event handler, the `Subject` and `Body` TextBoxes' `Text` properties are cleared out so that the user's values are not persisted across the postback.

Go ahead and test out this page in a browser. Since this page is in the `Membership` folder it is not accessible to anonymous visitors. Therefore, you will need to first log on (if you have not already). Enter a value into the `Subject` and `Body` TextBoxes and click the `PostCommentButton` button. This will cause a new record to be added to `GuestbookComments`. On postback, the subject and body you provided are wiped from the TextBoxes.

After clicking the `PostCommentButton` button there is no visual feedback that the comment was added to the guestbook. We still need to update this page to display the existing guestbook comments, which we will do in Step 5. Once we accomplish that, the just-added comment will appear in the list of comments, providing adequate visual feedback. For now, confirm that your guestbook comment was saved by examining the contents of the `GuestbookComments` table.

Figure 17 shows the contents of the `GuestbookComments` table after two comments have been left.

Figure 17: You Can See the Guestbook Comments in the `GuestbookComments` Table (Click to view full-size image)

> **NOTE**
>
> If a user attempts to insert a guestbook comment that contains potentially dangerous markup – such as HTML – ASP.NET will throw an `HttpRequestValidationException`. To learn more about this exception, why it's thrown, and how to permit users to submit potentially dangerous values, consult the Request Validation Whitepaper.

Step 5: Listing the Existing Guestbook Comments

In addition to leaving comments, a user visiting the `Guestbook.aspx` page should also be able to view the guestbook's existing comments. To accomplish this, add a ListView control named `CommentList` to the bottom of the page.

> **NOTE**
>
> The ListView control is new to ASP.NET version 3.5. It is designed to display a list of items in a very customizable and flexible layout, yet still offer built-in editing, inserting, deleting, paging, and sorting functionality like the GridView. If you are using ASP.NET 2.0, you will need to use the DataList or Repeater control instead. For more information on using the ListView, see Scott Guthrie's blog entry, The asp:ListView Control, and my article, Displaying Data with the ListView Control.

Open the ListView's Smart Tag and, from the Choose Data Source drop-down list, bind the control to a new data source. As we saw in Step 2, this will launch the Data Source Configuration Wizard. Select the Database icon, name the resulting SqlDataSource `CommentsDataSource`, and click OK. Next, select the `SecurityTutorialsConnectionString` connection string from the drop-down list and click Next.

At this point in Step 2 we specified the data to query by picking the `UserProfiles` table from the drop-down list and selecting the columns to return (refer back to Figure 9). This time, however, we want to craft a SQL statement that pulls back not only the records from `GuestbookComments`, but also the commenter's home town, homepage, signature, and username. Therefore, select the "Specify a custom SQL statement or stored procedure" radio button and click Next.

This will bring up the "Define Custom Statements or Stored Procedures" screen. Click the Query Builder button to graphically build the query. The Query Builder starts by prompting us to specify the tables we want to query from. Select the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` tables and click OK. This will add all three tables to the design surface. Since there are foreign key constraints amongst the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` tables, the Query Builder automatically `JOIN`s these tables.

All that remains is to specify the columns to return. From the `GuestbookComments` table select the `Subject`, `Body`, and `CommentDate` columns; return the `HomeTown`, `HomepageUrl`, and `Signature` columns from the `UserProfiles` table; and return `UserName` from `aspnet_Users`. Also, add "`ORDER BY CommentDate DESC`" to the end of the `SELECT` query so that the most recent posts are returned first. After making these selections, your Query Builder interface should look similar to the screen shot in Figure 18.

Figure 18: The Constructed Query `JOIN` s the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` Tables (Click to view full-size image)

Click OK to close the Query Builder window and return to the "Define Custom Statements or Stored Procedures" screen. Click Next to advance to the "Test Query" screen, where you may view the query results by clicking the Test Query button. When you're ready, click Finish to complete the Configure Data Source wizard.

When we completed the Configure Data Source wizard in Step 2, the associated DetailsView control's `Fields` collection was updated to include a BoundField for each column returned by the `SelectCommand`. The ListView, however, remains unchanged; we still need to define its layout. The ListView's layout can be constructed manually through its declarative markup or from the "Configure ListView" option in its Smart Tag. I usually prefer defining the markup by hand, but use whatever method is most natural to you.

I ended up using the following `LayoutTemplate`, `ItemTemplate`, and `ItemSeparatorTemplate` for my ListView control:

```
<asp:ListView ID="CommentList" runat="server" DataSourceID="CommentsDataSource">
     <LayoutTemplate>
          <span ID="itemPlaceholder" runat="server" />
          <p>
               <asp:DataPager ID="DataPager1" runat="server">
                    <Fields>
                         <asp:NextPreviousPagerField ButtonType="Button"
                              ShowFirstPageButton="True"
                              ShowLastPageButton="True" />
                    </Fields>
               </asp:DataPager>
          </p>
     </LayoutTemplate>
     <ItemTemplate>
          <h4><asp:Label ID="SubjectLabel" runat="server"
               Text='<%# Eval("Subject") %>' /></h4>
          <asp:Label ID="BodyLabel" runat="server"
               Text='<%# Eval("Body").ToString().Replace(Environment.NewLine, "<br />") %>' />
          <p>
               ---<br />
               <asp:Label ID="SignatureLabel" Font-Italic="true" runat="server"
                    Text='<%# Eval("Signature") %>' />
               <br />
               <br />
               My Home Town:
               <asp:Label ID="HomeTownLabel" runat="server"
                    Text='<%# Eval("HomeTown") %>' />
               <br />
               My Homepage:
               <asp:HyperLink ID="HomepageUrlLink" runat="server"
                    NavigateUrl='<%# Eval("HomepageUrl") %>'
                    Text='<%# Eval("HomepageUrl") %>' />
          </p>
          <p align="center">
               Posted by
               <asp:Label ID="UserNameLabel" runat="server"
                    Text='<%# Eval("UserName") %>' /> on
               <asp:Label ID="CommentDateLabel" runat="server"
                    Text='<%# Eval("CommentDate") %>' />
          </p>
     </ItemTemplate>
     <ItemSeparatorTemplate>
          <hr />
     </ItemSeparatorTemplate>
</asp:ListView>
```

The `LayoutTemplate` defines the markup emitted by the control, while the `ItemTemplate` renders each item returned by the SqlDataSource. The `ItemTemplate`'s resulting markup is placed in the `LayoutTemplate`'s `itemPlaceholder` control. In addition to the `itemPlaceholder`, the `LayoutTemplate` includes a DataPager control, which limits the ListView to showing just 10 guestbook comments per page (the default) and renders a paging interface.

My `ItemTemplate` displays each guestbook comment's subject in an `<h4>` element with the body situated below the subject. Note that syntax used for displaying the body takes the data returned by the `Eval("Body")` databinding statement, converts it to a string, and replaces line breaks with the `<br />` element. This conversion is needed in order to show the line breaks entered when submitting the comment since whitespace is ignored by HTML. The user's signature is displayed beneath the body in italics, followed by the user's home town, a link to his homepage, the date and time the comment was made, and the username of the person who left the comment.

Take a moment to view the page through a browser. You should see the comments that you added to the guestbook in Step 5 displayed here.

Figure 19: `Guestbook.aspx` Now Displays the Guestbook's Comments (Click to view full-size image)

Try adding a new comment to the guestbook. Upon clicking the `PostCommentButton` button the page posts back and the comment is added to the database, but the ListView control is not updated to show the new comment. This can be fixed by either:

- Updating the `PostCommentButton` button's `Click` event handler so that it invokes the ListView control's `DataBind()` method after inserting the new comment into the database, or
- Setting the ListView control's `EnableViewState` property to `false`. This approach works because by disabling the control's view state, it must rebind to the underlying data on every postback.

The tutorial website downloadable from this tutorial illustrates both techniques. The ListView control's `EnableViewState` property to `false` and the code needed to programmatically rebind the data to the ListView is present in the `Click` event handler, but is commented out.

> **NOTE**
>
> Currently the `AdditionalUserInfo.aspx` page allows the user to view and edit their home town, homepage, and signature settings. It might be nice to update `AdditionalUserInfo.aspx` to display the logged in user's guestbook comments. That is, in addition to examining and modifying her information, a user can visit the `AdditionalUserInfo.aspx` page to see what guestbook comments she's made in the past. I leave this as an exercise for the interested reader.

Step 6: Customizing the CreateUserWizard Control to Include an Interface for the Home Town, Homepage, and Signature

The `SELECT` query used by the `Guestbook.aspx` page uses an `INNER JOIN` to combine the related records amongst the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` tables. If a user that has no record in `UserProfiles` makes a guestbook comment, the comment won't be displayed in the ListView because the `INNER JOIN` only returns `GuestbookComments` records when there are matching records in `UserProfiles` and `aspnet_Users`. And as we saw in Step 3, if a user does not have a record in `UserProfiles` she cannot view or edit her settings in the `AdditionalUserInfo.aspx` page.

Needless to say, due to our design decisions it is important that every user account in the Membership system have a matching record in the `UserProfiles` table. What we want is for a corresponding record to be added to `UserProfiles` whenever a new Membership user account is created through the CreateUserWizard.

As discussed in the *Creating User Accounts* tutorial, after the new Membership user account is created the CreateUserWizard control raises its `CreatedUser` event. We can create an event handler for this event, get the UserId for the just-created user, and then insert a record into the `UserProfiles` table with default values for the `HomeTown`, `HomepageUrl`, and `Signature` columns. What's more, it is possible to prompt the user for these values by customizing the CreateUserWizard control's interface to include additional TextBoxes.

Let's first look at how to add a new row to the `UserProfiles` table in the `CreatedUser` event handler with default values. Following that, we will see how to customize the CreateUserWizard control's user interface to include additional form fields to collect the new user's home town, homepage, and signature.

Adding a Default Row to `UserProfiles`

In the *Creating User Accounts* tutorial we added a CreateUserWizard control to the `CreatingUserAccounts.aspx` page in the `Membership` folder. In order to have the CreateUserWizard control add a record to `UserProfiles` table upon user account creation, we need to update the CreateUserWizard control's functionality. Rather than making these changes to the `CreatingUserAccounts.aspx` page, let's instead add a new CreateUserWizard control to `EnhancedCreateUserWizard.aspx` page and make the modifications for this tutorial there.

Open the `EnhancedCreateUserWizard.aspx` page in Visual Studio and drag a CreateUserWizard control from the Toolbox onto the page. Set the CreateUserWizard control's `ID` property to `NewUserWizard`. As we discussed in the *Creating User Accounts* tutorial, the CreateUserWizard's default user interface prompts the visitor for the necessary information. Once this information has been supplied, the control internally creates a new user account in the Membership framework, all without us having to write a single line of code.

The CreateUserWizard control raises a number of events during its workflow. After a visitor supplies the request information and submits the form, the CreateUserWizard control initially fires its `CreatingUser` event. If there is a problem during the create process, the `CreateUserError` event is fired; however, if the user is successfully created, then the `CreatedUser` event is raised. In the *Creating User Accounts* tutorial we created an event handler for the `CreatingUser` event to ensure that the supplied username did not contain any leading or trailing spaces, and that the username did not appear anywhere in the password.

In order to add a row in the `UserProfiles` table for the just-created user, we need to create an event handler for the `CreatedUser` event. By the time the `CreatedUser` event has fired, the user account has already been created in the Membership framework, enabling us to retrieve the account's UserId value.

Create an event handler for the `NewUserWizard`'s `CreatedUser` event and add the following code:

```
protected void NewUserWizard_CreatedUser(object sender, EventArgs e)
{
     // Get the UserId of the just-added user
     MembershipUser newUser = Membership.GetUser(NewUserWizard.UserName);
     Guid newUserId = (Guid)newUser.ProviderUserKey;

     // Insert a new record into UserProfiles
     string connectionString =
          ConfigurationManager.ConnectionStrings["SecurityTutorialsConnectionString"].ConnectionString;
     string insertSql = "INSERT INTO UserProfiles(UserId, HomeTown, HomepageUrl,
          Signature) VALUES(@UserId, @HomeTown, @HomepageUrl, @Signature)";

     using (SqlConnection myConnection = new SqlConnection(connectionString))
     {
          myConnection.Open();
          SqlCommand myCommand = new SqlCommand(insertSql, myConnection);
          myCommand.Parameters.AddWithValue("@UserId", newUserId);
          myCommand.Parameters.AddWithValue("@HomeTown", DBNull.Value);
          myCommand.Parameters.AddWithValue("@HomepageUrl", DBNull.Value);
          myCommand.Parameters.AddWithValue("@Signature", DBNull.Value);
          myCommand.ExecuteNonQuery();
          myConnection.Close();
     }
}
```

The above code beings by retrieving the UserId of the just-added user account. This is accomplished by using the `Membership.GetUser(username)` method to return information about a particular user, and then using the `ProviderUserKey` property to retrieve their UserId. The username entered by the user in the CreateUserWizard control is available via its `UserName` property.

Next, the connection string is retrieved from `Web.config` and the `INSERT` statement is specified. The necessary ADO.NET objects are instantiated and the command executed. The code assigns a `DBNull` instance to the `@HomeTown`, `@HomepageUrl`, and `@Signature` parameters, which has the effect of inserting database `NULL` values for the `HomeTown`, `HomepageUrl`, and `Signature` fields.

Visit the `EnhancedCreateUserWizard.aspx` page through a browser and create a new user account. After doing so, return to Visual Studio and examine the contents of the `aspnet_Users` and `UserProfiles` tables (like we did back in Figure 12). You should see the new user account in `aspnet_Users` and a corresponding `UserProfiles` row (with `NULL` values for `HomeTown`, `HomepageUrl`, and `Signature`).

Figure 20: A New User Account and `UserProfiles` Record Have Been Added (Click to view full-size image)

After the visitor has supplied his new account information and clicked the "Create User" button, the user account is created and a row added to the `UserProfiles` table. The CreateUserWizard then displays its `CompleteWizardStep`, which displays a success message and a Continue button. Clicking the Continue button causes a postback, but no action is taken, leaving the user stuck on the `EnhancedCreateUserWizard.aspx` page.

We can specify a URL to send the user to when the Continue button is clicked via the CreateUserWizard control's `ContinueDestinationPageUrl` property. Set the `ContinueDestinationPageUrl` property to "~/Membership/AdditionalUserInfo.aspx". This takes the new user to `AdditionalUserInfo.aspx`, where they can view and update their settings.

Customizing the CreateUserWizard's Interface to Prompt for the New User's Home Town, Homepage, and Signature

The CreateUserWizard control's default interface is sufficient for simple account creation scenarios where only core user account information like username, password, and email need be collected. But what if we wanted to prompt the visitor to enter her home town, homepage, and signature while creating her account? It is possible to customize the CreateUserWizard control's interface to collect additional information at signup, and this information may be used in the `CreatedUser` event handler to insert additional records into the underlying database.

The CreateUserWizard control extends the ASP.NET Wizard control, which is a control that allows a page developer to define a series of ordered `WizardSteps`. The Wizard control renders the active step and provides a navigation interface that allows the visitor to move through these steps. The Wizard control is ideal for breaking down a long task into several short steps. For more information on the Wizard control, see Creating a Step-by-Step User Interface with the ASP.NET 2.0 Wizard Control.

The CreateUserWizard control's default markup defines two `WizardSteps`: `CreateUserWizardStep` and `CompleteWizardStep`.

```
<asp:CreateUserWizard ID="NewUserWizard" runat="server"
     ContinueDestinationPageUrl="~/Membership/AdditionalUserInfo.aspx">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

The first `WizardStep`, `CreateUserWizardStep`, renders the interface that prompts for the username, password, email, and so on. After the visitor supplies this information and clicks "Create User", she is shown the `CompleteWizardStep`, which shows the success message and a Continue button.

To customize the CreateUserWizard control's interface to include additional form fields, we can:

- **Create one or more new `WizardStep`s to contain the additional user interface elements**. To add a new `WizardStep` to the CreateUserWizard, click the "Add/Remove `WizardSteps`" link from its Smart Tag to launch the `WizardStep` Collection Editor. From there you can add, remove, or reorder the steps in the wizard. This is the approach we will use for this tutorial.
- **Convert the `CreateUserWizardStep` into an editable `WizardStep`**. This replaces the `CreateUserWizardStep` with an equivalent `WizardStep` whose markup defines a user interface that matches the `CreateUserWizardStep`'s. By converting the `CreateUserWizardStep` into a `WizardStep` we can reposition the controls or add additional user interface elements to this step. To convert the `CreateUserWizardStep` or `CompleteWizardStep` into an editable `WizardStep`, click the "Customize Create User Step" or "Customize Complete Step" link from the control's Smart Tag.

- Use some combination of the above two options.

One important thing to keep in mind is that the CreateUserWizard control executes its user account creation process when the "Create User" button is clicked from within its `CreateUserWizardStep`. It doesn't matter if there are additional `WizardStep` s after the `CreateUserWizardStep` or not.

When adding a custom `WizardStep` to the CreateUserWizard control to collect additional user input, the custom `WizardStep` can be placed before or after the `CreateUserWizardStep`. If it comes before the `CreateUserWizardStep` then the additional user input collected from the custom `WizardStep` is available for the `CreatedUser` event handler. However, if the custom `WizardStep` comes after `CreateUserWizardStep` then by the time the custom `WizardStep` is displayed the new user account has already been created and the `CreatedUser` event has already fired.

Figure 21 shows the workflow when the added `WizardStep` precedes the `CreateUserWizardStep`. Since the additional user information has been collected by the time the `CreatedUser` event fires, all we have to do is update the `CreatedUser` event handler to retrieve these inputs and use those for the `INSERT` statement's parameter values (rather than `DBNull.Value`).

Figure 21: The CreateUserWizard Workflow When an Additional `WizardStep` Precedes the `CreateUserWizardStep` (Click to view full-size image)

If the custom `WizardStep` is placed *after* the `CreateUserWizardStep`, however, the create user account process occurs before the user has had a chance to enter her home town, homepage, or signature. In such a case, this additional information needs to be inserted into the database after the user account has been created, as Figure 22 illustrates.

Figure 22: The CreateUserWizard Workflow When an Additional `WizardStep` Comes After the `CreateUserWizardStep` (Click to view full-size image)

The workflow shown in Figure 22 waits to insert a record into the `UserProfiles` table until after Step 2 completes. If the visitor closes her browser after step 1, however, we will have reached a state where a user account was created, but no record was added to `UserProfiles`. One workaround is to have a record with `NULL` or default values inserted into `UserProfiles` in the `CreatedUser` event handler (which fires after step 1), and then update this record after step 2 completes. This ensures that a `UserProfiles` record will be added for the user account even if the user quits the registration process midway through.

For this tutorial let's create a new `WizardStep` that occurs after the `CreateUserWizardStep` but before the `CompleteWizardStep`. Let's first get the WizardStep in place and configured and then we'll look at the code.

From the CreateUserWizard control's Smart Tag, select the "Add/Remove `WizardStep` s", which brings up the `WizardStep` Collection Editor dialog. Add a new `WizardStep`, setting its `ID` to `UserSettings`, its `Title` to "Your Settings" and its `StepType` to `Step`. Then position it so that it comes after the `CreateUserWizardStep` ("Sign Up for Your New Account") and before the `CompleteWizardStep` ("Complete"), as shown in Figure 23.

Figure 23: Add a New `WizardStep` to the CreateUserWizard Control (Click to view full-size image)

Click OK to close the `WizardStep` Collection Editor dialog. The new `WizardStep` is evidenced by the CreateUserWizard control's updated declarative markup:

```
<asp:CreateUserWizard ID="NewUserWizard" runat="server"
     ContinueDestinationPageUrl="~/Membership/AdditionalUserInfo.aspx">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:WizardStep runat="server" ID="UserSettings" StepType="Step"
               Title="Your Settings">
          </asp:WizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

Note the new `<asp:WizardStep>` element. We need to add the user interface to collect the new user's home town, homepage, and signature here. You can enter this content in the declarative syntax or through the Designer. To use the Designer, select the "Your Settings" step from the drop-down list in the Smart Tag to see the step in the Designer.

> **NOTE**
>
> Selecting a step through the Smart Tag's drop-down list updates the CreateUserWizard control's `ActiveStepIndex` property, which specifies the index of the starting step. Therefore, if you use this drop-down list to edit the "Your Settings" step in the Designer, be sure to set it back to "Sign Up for Your New Account" so that this step is shown when users first visit the `EnhancedCreateUserWizard.aspx` page.

Create a user interface within the "Your Settings" step that contains three TextBox controls named `HomeTown`, `HomepageUrl`, and `Signature`. After constructing this interface, the CreateUserWizard's declarative markup should look similar to the following:

```
<asp:CreateUserWizard ID="NewUserWizard" runat="server"
     ContinueDestinationPageUrl="~/Membership/AdditionalUserInfo.aspx">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:WizardStep runat="server" ID="UserSettings" StepType="Step"
               Title="Your Settings">
               <p>
                    <b>Home Town:</b><br />
                    <asp:TextBox ID="HomeTown" runat="server"></asp:TextBox>
               </p>
               <p>
                    <b>Homepage URL:</b><br />
                    <asp:TextBox ID="HomepageUrl" Columns="40" runat="server"></asp:TextBox>
               </p>
               <p>
                    <b>Signature:</b><br />
                    <asp:TextBox ID="Signature" TextMode="MultiLine" Width="95%"
                         Rows="5" runat="server"></asp:TextBox>
               </p>
          </asp:WizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

Go ahead and visit this page through a browser and create a new user account, specifying values for the home town, homepage, and signature. After completing the `CreateUserWizardStep` the user account is created in the Membership framework and the `CreatedUser` event handler runs, which adds a new row to `UserProfiles`, but with a database `NULL` value for `HomeTown`, `HomepageUrl`, and `Signature`. The values entered for the home town, homepage, and signature are never used. The net result is a new user account with a `UserProfiles` record whose `HomeTown`, `HomepageUrl`, and `Signature` fields have yet to be specified.

We need to execute code after the "Your Settings" step that takes the home town, honepage, and signature values entered by the user and updates the appropriate `UserProfiles` record. Each time the user moves between steps in a Wizard control, the Wizard's `ActiveStepChanged` event fires. We can create an event handler for this event and update the `UserProfiles` table when the "Your Settings" step has completed.

Add an event handler for the CreateUserWizard's `ActiveStepChanged` event and add the following code:

```
protected void NewUserWizard_ActiveStepChanged(object sender, EventArgs e)
{
     // Have we JUST reached the Complete step?
     if (NewUserWizard.ActiveStep.Title == "Complete")
     {
          WizardStep UserSettings = NewUserWizard.FindControl("UserSettings") as
          WizardStep;

          // Programmatically reference the TextBox controls
          TextBox HomeTown = UserSettings.FindControl("HomeTown") as TextBox;
          TextBox HomepageUrl = UserSettings.FindControl("HomepageUrl") as TextBox;
          TextBox Signature = UserSettings.FindControl("Signature") as TextBox;

          // Update the UserProfiles record for this user
          // Get the UserId of the just-added user
          MembershipUser newUser = Membership.GetUser(NewUserWizard.UserName);
          Guid newUserId = (Guid)newUser.ProviderUserKey;

          // Insert a new record into UserProfiles
          string connectionString =
               ConfigurationManager.ConnectionStrings["SecurityTutorialsConnectionString"].ConnectionString;
          string updateSql = "UPDATE UserProfiles SET HomeTown = @HomeTown, HomepageUrl
               = @HomepageUrl, Signature = @Signature WHERE UserId = @UserId";

          using (SqlConnection myConnection = new SqlConnection(connectionString))
          {
               myConnection.Open();
               SqlCommand myCommand = new SqlCommand(updateSql, myConnection);
               myCommand.Parameters.AddWithValue("@HomeTown", HomeTown.Text.Trim());
               myCommand.Parameters.AddWithValue("@HomepageUrl", HomepageUrl.Text.Trim());
               myCommand.Parameters.AddWithValue("@Signature", Signature.Text.Trim());
               myCommand.Parameters.AddWithValue("@UserId", newUserId);
               myCommand.ExecuteNonQuery();
               myConnection.Close();
          }
     }
}
```

The above code starts by determining if we have just reached the "Complete" step. Since the "Complete" step occurs immediately after the "Your Settings" step, then when the visitor reaches "Complete" step that means she just finished the "Your Settings" step.

In such a case, we need to programmatically reference the TextBox controls within the `UserSettings WizardStep`. This is accomplished by first using the `FindControl` method to programmatically referencing the `UserSettings WizardStep`, and then again to reference the TextBoxes from within the `WizardStep`. Once the TextBoxes have been referenced, we're ready to execute the `UPDATE` statement. The `UPDATE` statement has the same number of parameters as the `INSERT` statement in the `CreatedUser` event handler, but here we use the home town, homepage, and signature values supplied by the user.

With this event handler in place, visit the `EnhancedCreateUserWizard.aspx` page through a browser and create a new user account specifying values for the home town, homepage, and signature. After creating the new account you should be redirected to the `AdditionalUserInfo.aspx` page, where the just-entered home town, homepage, and signature information is displayed.

NOTE

Our website currently has two pages from which a visitor can create a new account: `CreatingUserAccounts.aspx` and `EnhancedCreateUserWizard.aspx`. The website's sitemap and login page point to the `CreatingUserAccounts.aspx` page, but the `CreatingUserAccounts.aspx` page does not prompt the user for their home town, homepage, and signature information and does not add a corresponding row to `UserProfiles`. Therefore, either update the `CreatingUserAccounts.aspx` page so that it offers this functionality or update the sitemap and login page to reference `EnhancedCreateUserWizard.aspx` instead of `CreatingUserAccounts.aspx`. If you choose the latter option, be sure to update the `Membership` folder's `Web.config` file so as to allow anonymous users access to the `EnhancedCreateUserWizard.aspx` page.

Summary

In this tutorial we looked at techniques for modeling data that is related to user accounts within the Membership framework. In particular, we looked at modeling entities that share a one-to-many relationship with user accounts as well as data that shares a one-to-one relationship. Furthermore, we saw how this related information could be displayed, inserted, and updated, with some examples using the SqlDataSource control and others using ADO.NET code.

This tutorial completes our look at user accounts. Starting with the next tutorial we will turn our attention to roles. Over the next several tutorials we will look at the Roles framework, see how to create new roles, how to assign roles to users, how to determine what roles a user belongs to, and how to apply role-based authorization.

Happy Programming!

Creating the Membership Schema in SQL Server (VB)

9/16/2020 • 27 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

This tutorial starts by examining techniques for adding the necessary schema to the database in order to use the SqlMembershipProvider. Following that, we will examine the key tables in the schema and discuss their purpose and importance. This tutorial ends with a look at how to tell an ASP.NET application which provider the Membership framework should use.

Introduction

The previous two tutorials examined using forms authentication to identify website visitors. The forms authentication framework makes it easy for developers to log a user into a website and to remember them across page visits through the use of authentication tickets. The `FormsAuthentication` class includes methods for generating the ticket and adding it to the visitor's cookies. The `FormsAuthenticationModule` examines all incoming requests and, for those with a valid authentication ticket, creates and associates a `GenericPrincipal` and a `FormsIdentity` object with the current request. Forms authentication is merely a mechanism for granting an authentication ticket to a visitor when logging in and, on subsequent requests, parsing that ticket to determine the user's identity. For a web application to support user accounts, we still need to implement a user store and add functionality to validate credentials, register new users, and the myriad of other user account-related tasks.

Prior to ASP.NET 2.0, developers were on the hook for implementing all of these user account-related tasks. Fortunately the ASP.NET team recognized this shortcoming and introduced the Membership framework with ASP.NET 2.0. The Membership framework is a set of classes in the .NET Framework that provide a programmatic interface for accomplishing core user account-related tasks. This framework is built atop the provider model, which allows developers to plug a customized implementation into a standardized API.

As discussed in the *Security Basics and ASP.NET Support* tutorial, the .NET Framework ships with two built-in Membership providers: `ActiveDirectoryMembershipProvider` and `SqlMembershipProvider`. As its name implies, the `SqlMembershipProvider` uses a Microsoft SQL Server database as the user store. In order to use this provider in an application, we need to tell the provider what database to use as the store. As you might imagine, the `SqlMembershipProvider` expects the user store database to have certain database tables, views, and stored procedures. We need to add this expected schema to the selected database.

This tutorial starts by examining techniques for adding the necessary schema to the database in order to use the `SqlMembershipProvider`. Following that, we will examine the key tables in the schema and discuss their purpose and importance. This tutorial ends with a look at how to tell an ASP.NET application which provider the Membership framework should use.

Let's get started!

Step 1: Deciding Where to Place the User Store

An ASP.NET application's data is commonly stored in a number of tables in a database. When implementing the `SqlMembershipProvider` database schema we must decide whether to place the Membership schema in the

same database as the application data or in an alternate database.

I recommend locating the Membership schema in the same database as the application data for the following reasons:

- **Maintainability** an application whose data is encapsulated in one database is easier to understand, maintain, and deploy than an application that has two separate databases.
- **Relational Integrity** by locating the Membership-related tables in the same database as the application tables it is possible to establish foreign key constraints between the primary keys in the Membership-related tables and related application tables.

Decoupling the user store and application data into separate databases only makes sense if you have multiple applications that each use separate databases, but need to share a common user store.

Creating a Database

The application we have been building since the second tutorial has not yet needed a database. We need one now, however, for the user store. Let's create one and then add to it the schema required by the `SqlMembershipProvider` provider (see Step 2).

> **NOTE**
>
> Throughout this tutorial series we will be using a Microsoft SQL Server 2005 Express Edition database to store our application tables and the `SqlMembershipProvider` schema. This decision was made for two reasons: first, due to its cost - free - the Express Edition is the most readably accessible version of SQL Server 2005; second, SQL Server 2005 Express Edition databases can be placed directly in the web application's `App_Data` folder, making it a cinch to package the database and web application together in one ZIP file and to redeploy it without any special setup instructions or configuration options. If you'd prefer to follow along using a non-Express Edition version of SQL Server, feel free. The steps are virtually identical. The `SqlMembershipProvider` schema will work with any version of Microsoft SQL Server 2000 and up.

From the Solution Explorer, right-click on the `App_Data` folder and choose to Add New Item. (If you do not see an `App_Data` folder in your project, right-click on the project in Solution Explorer, select Add ASP.NET Folder, and pick `App_Data`.) From the Add New Item dialog box, choose to add a new SQL Database named `SecurityTutorials.mdf`. In this tutorial we will add the `SqlMembershipProvider` schema to this database; in subsequent tutorials we will create additional tables to capture our application data.

Figure 1: Add a New SQL Database Named `SecurityTutorials.mdf` Database to the `App_Data` Folder (Click to view full-size image)

Adding a database to the `App_Data` folder automatically includes it in the Database Explorer view. (In the non-Express Edition version of Visual Studio, the Database Explorer is called the Server Explorer.) Go to the Database Explorer and expand the just-added `SecurityTutorials` database. If you do not see the Database Explorer on screen, go to the View menu and choose Database Explorer, or hit Ctrl+Alt+S. As Figure 2 shows, the `SecurityTutorials` database is empty - it contains no tables, no views, and no stored procedures.

Figure 2: The `SecurityTutorials` Database is Currently Empty (Click to view full-size image)

Step 2: Adding the `SqlMembershipProvider` Schema to the Database

The `SqlMembershipProvider` requires a particular set of tables, views, and stored procedures to be installed in the user store database. These requisite database objects can be added using the `aspnet_regsql.exe` tool. This file is located in the `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\` folder.

> **NOTE**
>
> The `aspnet_regsql.exe` tool offers both command line functionality and a graphical user interface. The graphical interface is more user friendly and is what we will examine in this tutorial. The command line interface is useful when the addition of the `SqlMembershipProvider` schema needs to be automated, such as in build scripts or automated testing scenarios.

The `aspnet_regsql.exe` tool is used to add or remove *ASP.NET application services* to a specified SQL Server database. The ASP.NET application services encompass the schemas for the `SqlMembershipProvider` and `SqlRoleProvider`, along with the schemas for the SQL-based providers for other ASP.NET 2.0 frameworks. We need to provide two bits of information to the `aspnet_regsql.exe` tool:

- Whether we want to add or remove application services, and
- The database from which to add or remove the application services schema

In prompting for the database to use, the `aspnet_regsql.exe` tool asks us to provide the name of the server the database resides on, the security credentials for connecting to the database, and the database name. If you are using the non-Express Edition of SQL Server, you should already know this information, as it is the same information you must provide through a connection string when working with the database through an ASP.NET web page. Determining the server and database name when using a SQL Server 2005 Express Edition database in the `App_Data` folder, however, is a bit more involved.

The following section examines a straightforward way for specifying the server and database name for a SQL Server 2005 Express Edition database in the `App_Data` folder. If you are not using SQL Server 2005 Express Edition feel free to skip ahead to the Installing the Application Services section.

Determining the Server and Database Name for a SQL Server 2005 Express Edition Database in the `App_Data` Folder

In order to use the `aspnet_regsql.exe` tool we need to know the server and database names. The server name

is `localhost\InstanceName`. Most likely, the *InstanceName* is `SQLExpress`. However, if you installed SQL Server 2005 Express Edition manually (that is, you did not install it automatically while installing Visual Studio), then it is possible that you selected a different instance name.

The database name is a bit trickier to determine. Databases in the `App_Data` folder typically have a database name that includes a globally unique identifier along with the path to the database file. We need to determine this database name in order to add the application services schema through `aspnet_regsql.exe`.

The easiest way to ascertain the database name is to examine it through SQL Server Management Studio. SQL Server Management Studio provides a graphical interface for managing SQL Server 2005 databases, but it does not ship with the Express Edition of SQL Server 2005. The good news is that you can download the free Express Edition of SQL Server Management Studio.

> **NOTE**
> If you also have a non-Express Edition version of SQL Server 2005 installed on your desktop then the full version of Management Studio is likely installed. You can use the full version to determine the database name, following the same steps as outlined below for the Express Edition.

Start by closing Visual Studio to ensure that any locks imposed by Visual Studio on the database file are closed. Next, launch SQL Server Management Studio and connect to the `localhost\InstanceName` database for SQL Server 2005 Express Edition. As noted earlier, chances are the instance name is `SQLExpress`. For the Authentication option, select Windows Authentication.

Figure 3: Connect to the SQL Server 2005 Express Edition Instance (Click to view full-size image)

After connecting to the SQL Server 2005 Express Edition instance, Management Studio displays folders for the Databases, the Security settings, the Server Objects, and so on. If you expand the Databases tab you will see that the `SecurityTutorials.mdf` database is *not* registered in the database instance - we need to attach the database first.

Right-click on the Databases folder and choose Attach from the context menu. This will display the Attach Databases dialog box. From here, click the Add button, browse to the `SecurityTutorials.mdf` database, and click OK. Figure 4 shows the Attach Databases dialog box after the `SecurityTutorials.mdf` database has been selected. Figure 5 shows Management Studio's Object Explorer after the database has been successfully attached.

Figure 4: Attach the `SecurityTutorials.mdf` Database (Click to view full-size image)

Figure 5: The `SecurityTutorials.mdf` Database Appears in the Databases Folder (Click to view full-size image)

As Figure 5 shows, the `SecurityTutorials.mdf` database has a rather abstruse name. Let's change it to a more memorable (and easier to type) name. Right-click on the database, choose Rename from the context menu, and rename it `SecurityTutorialsDatabase`. This does not change the filename, just the name the database uses to identify itself to SQL Server.

Figure 6: Rename the Database to `SecurityTutorialsDatabase` (Click to view full-size image)

At this point we know the server and database names for the `SecurityTutorials.mdf` database file: `localhost\InstanceName` and `SecurityTutorialsDatabase`, respectively. We are now ready to install the application services through the `aspnet_regsql.exe` tool.

Installing the Application Services

To launch the `aspnet_regsql.exe` tool, go to the start menu and choose Run. Enter `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\aspnet_regsql.exe` into the textbox and click OK. Alternatively, you can use Windows Explorer to drill down to the appropriate folder and double-click the `aspnet_regsql.exe` file. Either approach will net the same results.

Running the `aspnet_regsql.exe` tool without any command line arguments launches the ASP.NET SQL Server Setup Wizard graphical user interface. The wizard makes it easy to add or remove the ASP.NET application services on a specified database. The first screen of the wizard, shown in Figure 7, describes the purpose of the tool.

Figure 7: Use the ASP.NET SQL Server Setup Wizard Makes to Add the Membership Schema (Click to view full-size image)

The second step in the wizard asks us whether we want to add the application services or remove them. Since we want to add the tables, views, and stored procedures necessary for the `SqlMembershipProvider`, choose the Configure SQL Server for application services option. Later, if you want to remove this schema from your database, re-run this wizard, but instead choose the Remove application services information from an existing database option.

Figure 8: Choose the Configure SQL Server for Application Services Option (Click to view full-size image)

The third step prompts for the database information: the server name, authentication information, and the database name. If you have been following along with this tutorial and have added the `SecurityTutorials.mdf` database to `App_Data`, attached it to `localhost\InstanceName`, and renamed it to `SecurityTutorialsDatabase`, then use the following values:

- Server: `localhost\InstanceName`
- Windows authentication
- Database: `SecurityTutorialsDatabase`

Figure 9: Enter the Database Information (Click to view full-size image)

After entering the database information, click Next. The final step summarizes the steps that will be taken. Click Next to install the application services and then Finish to complete the wizard.

> **NOTE**
> If you used Management Studio to attach the database and rename the database file, be sure to detach the database and close Management Studio before reopening Visual Studio. To detach the `SecurityTutorialsDatabase` database, right-click on the database name and, from the Tasks menu, choose Detach.

Upon completion of the wizard, return to Visual Studio and navigate to the Database Explorer. Expand the Tables folder. You should see a series of tables whose names start with the prefix `aspnet_`. Likewise, a variety of views and stored procedures can be found under the Views and Stored Procedures folders. These database objects make up the application services schema. We will examine the membership- and role-specific database objects in Step 3.

Figure 10: A Variety of Tables, Views, and Stored Procedures Have Been Added to the Database (Click to view full-size image)

> **NOTE**
> The `aspnet_regsql.exe` tool's graphical user interface installs the entire application services schema. But when executing `aspnet_regsql.exe` from the command-line you can specify what particular application services components to install (or remove). Therefore, if you want to add just the tables, views, and stored procedures necessary for the `SqlMembershipProvider` and `SqlRoleProvider` providers, run `aspnet_regsql.exe` from the command-line. Alternatively, you can manually run the appropriate subset of T-SQL create scripts used by `aspnet_regsql.exe`. These scripts are located in the `WINDIR%\Microsoft.Net\Framework\v2.0.50727\` folder with names like `InstallCommon.sql`, `InstallMembership.sql`, `InstallRoles.sql`, `InstallProfile.sql`, `InstallSqlState.sql`, and so on.

At this point we have created the database objects needed by the `SqlMembershipProvider`. However, we still need to instruct the Membership framework that it should use the `SqlMembershipProvider` (versus, say, the `ActiveDirectoryMembershipProvider`) and that the `SqlMembershipProvider` should use the `SecurityTutorials` database. We'll look at how to specify what provider to use and how to customize the selected provider's

settings in Step 4. But first, let's take a deeper look at the database objects that were just created.

Step 3: A Look at the Schema's Core Tables

When working with the Membership and Roles frameworks in an ASP.NET application, the implementation details are encapsulated by the provider. In future tutorials we will interface with these frameworks via the .NET Framework's `Membership` and `Roles` classes. When using these high-level APIs we do not need to concern ourselves with the low-level details, like what queries are executed or what tables are modified by the `SqlMembershipProvider` and `SqlRoleProvider`.

Given this, we could confidently use the Membership and Roles frameworks without having explored the database schema created in Step 2. However, when creating the tables to store application data we may need to create entities that relate to users or roles. It helps to have a familiarity with the `SqlMembershipProvider` and `SqlRoleProvider` schemas when establishing foreign key constraints between the application data tables and those tables created in Step 2. Moreover, in certain rare circumstances we may need to interface with the user and role stores directly at the database level (instead of through the `Membership` or `Roles` classes).

Partitioning the User Store Into Applications

The Membership and Roles frameworks are designed such that a single user and role store can be shared among many different applications. An ASP.NET application that uses the Membership or Roles frameworks must specify what application partition to use. In short, multiple web applications can use the same user and role stores. Figure 11 depicts user and role stores that are partitioned into three applications: HRSite, CustomerSite, and SalesSite. These three web applications each have their own unique users and roles, yet they all physically store their user account and role information in the same database tables.

Figure 11: User Accounts May Be Partitioned Across Multiple Applications (Click to view full-size image)

The `aspnet_Applications` table is what defines these partitions. Each application that uses the database to store user account information is represented by a row in this table. The `aspnet_Applications` table has four columns: `ApplicationId`, `ApplicationName`, `LoweredApplicationName`, and `Description`. `ApplicationId` is of type `uniqueidentifier` and is the table's primary key; `ApplicationName` provides a unique human-friendly name for each application.

The other Membership- and Role-related tables link back to the `ApplicationId` field in `aspnet_Applications`. For example, the `aspnet_Users` table, which contains a record for each user account, has an `ApplicationId` foreign key field; ditto for the `aspnet_Roles` table. The `ApplicationId` field in these tables specifies the

application partition the user account or role belongs to.

Storing User Account Information

User account information is housed in two tables: `aspnet_Users` and `aspnet_Membership`. The `aspnet_Users` table contains fields that hold the essential user account information. The three most pertinent columns are:

- `UserId`
- `UserName`
- `ApplicationId`

`UserId` is the primary key (and of type `uniqueidentifier`). `UserName` is of type `nvarchar(256)` and, along with the password, makes up the user's credentials. (A user's password is stored in the `aspnet_Membership` table.) `ApplicationId` links the user account to a particular application in `aspnet_Applications`. There is a composite `UNIQUE` constraint on the `UserName` and `ApplicationId` columns. This ensures that in a given application each UserName is unique, yet it allows for the same `UserName` to be used in different applications.

The `aspnet_Membership` table includes additional user account information, like the user's password, email address, the last login date and time, and so forth. There is a one-to-one correspondence between records in the `aspnet_Users` and `aspnet_Membership` tables. This relationship is ensured by the `UserId` field in `aspnet_Membership`, which serves as the table's primary key. Like the `aspnet_Users` table, `aspnet_Membership` includes an `ApplicationId` field that ties this information to a particular application partition.

Securing Passwords

Password information is stored in the `aspnet_Membership` table. The `SqlMembershipProvider` allows for passwords to be stored in the database using one of the following three techniques:

- **Clear** - the password is stored in the database as plain-text. I strongly discourage using this option. If the database is compromised - be it by a hacker who finds a back door or a disgruntled employee who has database access - every single user's credentials are there for the taking.
- **Hashed** - passwords are hashed using a one-way hash algorithm and a randomly generated salt value. This hashed value (along with the salt) is stored in the database.
- **Encrypted** - an encrypted version of the password is stored in the database.

The password storage technique used depends on the `SqlMembershipProvider` settings specified in `Web.config`. We will look at customizing the `SqlMembershipProvider` settings in Step 4. The default behavior is to store the hash of the password.

The columns responsible for storing the password are `Password`, `PasswordFormat`, and `PasswordSalt`. `PasswordFormat` is a field of type `int` whose value indicates the technique used for storing the password: 0 for Clear; 1 for Hashed; 2 for Encrypted. `PasswordSalt` is assigned a randomly generated string regardless of the password storage technique used; the value of `PasswordSalt` is only used when computing the hash of the password. Finally, the `Password` column contains the actual password data, be it the plain-text password, the hash of the password, or the encrypted password.

Table 1 illustrates what these three columns might look like for the various storage techniques when storing the password MySecret! .

STORAGE TECHNIQUE<_O3A_P />	PASSWORD<_O3A_P />	PASSWORDFORMAT<_O3A_P />	PASSWORDSALT<_O3A_P />
Clear	MySecret!	0	tTnkPlesqissc2y2SMEygA==
Hashed	2oXm6sZHWbTHFgjgkGQsc2Ec9ZM=	1	wFgjUfhdUFOCKQiI61vtiQ==

STORAGE TECHNIQUE<_O3A_P />	PASSWORD<_O3A_P />	PASSWORDFORMAT<_O3A_P />	PASSWORDSALT<_O3A_P />
Encrypted	62RZgDvhxykkqsMchZ0Yly7HS6onhpaoCYaRxV8g0F4CW56OXUU3e7Inza9j9BKp	2	LSRzhGS/aa/oqAXGLHJNBw==

Table 1: Example Values for the Password-Related Fields When Storing the Password MySecret!

> **NOTE**
>
> The particular encryption or hashing algorithm used by the `SqlMembershipProvider` is determined by the settings in the `<machineKey>` element. We discussed this configuration element in Step 3 of the *Forms Authentication Configuration and Advanced Topics* tutorial.

Storing Roles and Role Associations

The Roles framework allows developers to define a set of roles and specify what users belong to what roles. This information is captured in the database through two tables: `aspnet_Roles` and `aspnet_UsersInRoles`. Each record in the `aspnet_Roles` table represents a role for a particular application. Much like the `aspnet_Users` table, the `aspnet_Roles` table has three columns pertinent to our discussion:

- `RoleId`
- `RoleName`
- `ApplicationId`

`RoleId` is the primary key (and of type `uniqueidentifier`). `RoleName` is of type `nvarchar(256)`. And `ApplicationId` links the user account to a particular application in `aspnet_Applications`. There is a composite `UNIQUE` constraint on the `RoleName` and `ApplicationId` columns, ensuring that in a given application each role name is unique.

The `aspnet_UsersInRoles` table serves as a mapping between users and roles. There are only two columns - `UserId` and `RoleId` - and together they make up a composite primary key.

Step 4: Specifying the Provider and Customizing Its Settings

All of the frameworks that support the provider model - such as the Membership and Roles frameworks - lack implementation details themselves and instead delegate that responsibility to a provider class. In the case of the Membership framework, the `Membership` class defines the API for managing user accounts, but it does not interact directly with any user store. Rather, the `Membership` class's methods hand off the request to the configured provider - we will be using the `SqlMembershipProvider`. When we invoke one of the methods in the `Membership` class, how does the Membership framework know to delegate the call to the `SqlMembershipProvider`?

The `Membership` class has a `Providers` property that contains a reference to all of the registered provider classes available for use by the Membership framework. Each registered provider has an associated name and type. The name offers a human-friendly way to reference a particular provider in the `Providers` collection, while the type identifies the provider class. Moreover, each registered provider may include configuration settings. Configuration settings for the Membership framework include `PasswordFormat` and `requiresUniqueEmail`, among many others. See Table 2 for a complete list of configuration settings used by the `SqlMembershipProvider`.

The `Providers` property's contents are specified through the web application's configuration settings. By default, all web applications have a provider named `AspNetSqlMembershipProvider` of type `SqlMembershipProvider`. This default Membership provider is registered in `machine.config` (located at `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\CONFIG`):

```
<membership>
 <providers>
 <add name="AspNetSqlMembershipProvider"
 type="System.Web.Security.SqlMembershipProvider, System.Web, Version=2.0.0.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a"
 connectionStringName="LocalSqlServer"
 enablePasswordRetrieval="false"
 enablePasswordReset="true"
 requiresQuestionAndAnswer="true"
 applicationName="/"
 requiresUniqueEmail="false"
 passwordFormat="Hashed"
 maxInvalidPasswordAttempts="5"
 minRequiredPasswordLength="7"
 minRequiredNonalphanumericCharacters="1"
 passwordAttemptWindow="10"
 passwordStrengthRegularExpression=""/>
 </providers>
</membership>
```

As the markup above shows, the `<membership>` element defines the configuration settings for the Membership framework while the `<providers>` child element specifies the registered providers. Providers may be added or removed using the `<add>` or `<remove>` elements; use the `<clear>` element to remove all currently registered providers. As the markup above shows, `machine.config` adds a provider named `AspNetSqlMembershipProvider` of type `SqlMembershipProvider`.

In addition to the `name` and `type` attributes, the `<add>` element contains attributes that define the values for various configuring settings. Table 2 lists the available `SqlMembershipProvider`-specific configuration settings, along with a description of each.

NOTE

Any default values noted in Table 2 refer to the default values defined in the `SqlMembershipProvider` class. Note that not all of the configuration settings in `AspNetSqlMembershipProvider` correspond to the default values of the `SqlMembershipProvider` class. For example, if not specified in a Membership provider, the `requiresUniqueEmail` setting defaults to true. However, the `AspNetSqlMembershipProvider` overrides this default value by explicitly specifying a value of `false`.

SETTING<_O3A_P />	DESCRIPTION<_O3A_P />
`ApplicationName`	Recall that the Membership framework allows for a single user store to be partitioned across multiple applications. This setting indicates the name of the application partition used by the Membership provider. If this value is not explicitly specified, it is set, at runtime, to the value of the application's virtual root path.
`commandTimeout`	Specifies the SQL command timeout value (in seconds). The default value is 30.

SETTING<_O3A_P />	DESCRIPTION<_O3A_P />
`connectionStringName`	The name of the connection string in the `<connectionStrings>` element to use to connect to the user store database. This value is required.
`description`	Provides a human-friendly description of the registered provider.
`enablePasswordRetrieval`	Specifies whether users may retrieve their forgotten password. The default value is `false`.
`enablePasswordReset`	Indicates whether users are allowed to reset their password. Defaults to `true`.
`maxInvalidPasswordAttempts`	The maximum number of unsuccessful login attempts that may occur for a given user during the specified `passwordAttemptWindow` before the user is locked out. The default value is 5.
`minRequiredNonalphanumericCharacters`	The minimum number of non-alphanumeric characters that must appear in a user's password. This value must be between 0 and 128; the default is 1.
`minRequiredPasswordLength`	The minimum number of characters required in a password. This value must be between 0 and 128; the default is 7.
`name`	The name of the registered provider. This value is required.
`passwordAttemptWindow`	The number of minutes during which failed login attempts are tracked. If a user supplies invalid login credentials `maxInvalidPasswordAttempts` times within this specified window, they are locked out. The default value is 10.
`PasswordFormat`	The password storage format: `Clear`, `Hashed`, or `Encrypted`. The default is `Hashed`.
`passwordStrengthRegularExpression`	If provided, this regular expression is used to evaluate the strength of the user's selected password when creating a new account or when changing their password. The default value is an empty string.
`requiresQuestionAndAnswer`	Specifies whether a user must answer his security question when retrieving or resetting his password. The default value is `true`.
`requiresUniqueEmail`	Indicates whether all user accounts in a given application partition must have a unique email address. The default value is `true`.
`type`	Specifies the type of the provider. This value is required.

Table 2: Membership and `SqlMembershipProvider` Configuration Settings

In addition to `AspNetSqlMembershipProvider`, other Membership providers may be registered on an application-by-application basis by adding similar markup to the `Web.config` file.

> **NOTE**
> The Roles framework works in much the same way: there is a default registered role provider in `machine.config` and the registered providers may be customized on an application-by-application basis in `Web.config`. We will examine the Roles framework and its configuration markup in detail in a future tutorial.

Customizing the `SqlMembershipProvider` Settings

The default `SqlMembershipProvider` (`AspNetSqlMembershipProvider`) has its `connectionStringName` attribute set to `LocalSqlServer`. Like the `AspNetSqlMembershipProvider` provider, the connection string name `LocalSqlServer` is defined in `machine.config`.

```
<connectionStrings>
 <add name="LocalSqlServer"
 connectionString="data source=.\SQLEXPRESS;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User Instance=true"
 providerName="System.Data.SqlClient"/>
</connectionStrings>
```

As you can see, this connection string defines a SQL 2005 Express Edition database located at |DataDirectory|aspnetdb.mdf. The string |DataDirectory| is translated at runtime to point to the `~/App_Data/` directory, so the database path |DataDirectory|aspnetdb.mdf translates to `~/App_Data` / `aspnet.mdf`.

If we did not specify any Membership provider information in our application's `Web.config` file, the application uses the default registered Membership provider, `AspNetSqlMembershipProvider`. If the `~/App_Data/aspnet.mdf` database does not exist, the ASP.NET runtime will automatically create it and add the application services schema. However, we don't want to use the `aspnet.mdf` database; rather, we want to use the `SecurityTutorials.mdf` database we created in Step 2. This modification can be accomplished in one of two ways:

- **Specify a value for the `LocalSqlServer` connection string name in `Web.config`.** By overwriting the `LocalSqlServer` connection string name value in `Web.config`, we can use the default registered Membership provider (`AspNetSqlMembershipProvider`) and have it correctly work with the `SecurityTutorials.mdf` database. This approach is fine if you are content with the configuration settings specified by `AspNetSqlMembershipProvider`. For more information on this technique, see Scott Guthrie's blog post, Configuring ASP.NET 2.0 Application Services to Use SQL Server 2000 or SQL Server 2005.
- **Add a new registered provider of type `SqlMembershipProvider` and configure its `connectionStringName` setting to point to the `SecurityTutorials.mdf` database.** This approach is useful in scenarios where you want to customize other configuration properties in addition to the database connection string. In my own projects I always use this approach because of its flexibility and readability.

Before we can add a new registered provider that references the `SecurityTutorials.mdf` database, we first need to add an appropriate connection string value in the `<connectionStrings>` section in `Web.config`. The following markup adds a new connection string named `SecurityTutorialsConnectionString` that references the SQL Server 2005 Express Edition `SecurityTutorials.mdf` database in the `App_Data` folder.

```
<configuration>
 <connectionStrings>
 <add name="SecurityTutorialsConnectionString"
 connectionString="Data
Source=.\SQLEXPRESS;AttachDbFilename=|DataDirectory|\SecurityTutorials.mdf;Integrated Security=True;User
Instance=True"
 providerName="System.Data.SqlClient"/>
 </connectionStrings>
 <system.web>
 ... Configuration markup removed for brevity ...  </system.web>
</configuration>
```

> **NOTE**
> If you are using an alternate database file, update the connection string as needed. For more information on forming the correct connection string, refer to ConnectionStrings.com.

Next, add the following Membership configuration markup to the `Web.config` file. This markup registers a new provider named `SecurityTutorialsSqlMembershipProvider`.

```
<configuration>
 <connectionStrings>
 <add name="SecurityTutorialsConnectionString"
 connectionString="Data
Source=.\SQLEXPRESS;AttachDbFilename=|DataDirectory|\SecurityTutorials.mdf;Integrated Security=True;User
Instance=True"
 providerName="System.Data.SqlClient"/>
 </connectionStrings>
 <system.web>
 <membership defaultProvider="SecurityTutorialsSqlMembershipProvider">
 <providers>
 <!-- Add a customized SqlMembershipProvider -->
 <add name="SecurityTutorialsSqlMembershipProvider"
 type="System.Web.Security.SqlMembershipProvider"
 connectionStringName="SecurityTutorialsConnectionString"
 enablePasswordRetrieval="false"
 enablePasswordReset="true"
 requiresQuestionAndAnswer="true"
 applicationName="SecurityTutorials"
 requiresUniqueEmail="true"
 passwordFormat="Hashed"
 maxInvalidPasswordAttempts="5"
 minRequiredPasswordLength="7"
 minRequiredNonalphanumericCharacters="1"
 passwordAttemptWindow="10"
 passwordStrengthRegularExpression=""/>
 </providers>
 </membership>
 ... Configuration markup removed for brevity ...
 </system.web>
</configuration>
```

In addition to registering the `SecurityTutorialsSqlMembershipProvider` provider, the above markup defines the `SecurityTutorialsSqlMembershipProvider` as the default provider (via the `defaultProvider` attribute in the `<membership>` element). Recall that the Membership framework can have multiple registered providers. Since `AspNetSqlMembershipProvider` is registered as the first provider in `machine.config`, it serves as the default provider unless we indicate otherwise.

Currently, our application has two registered providers: `AspNetSqlMembershipProvider` and `SecurityTutorialsSqlMembershipProvider`. However, before registering the

`SecurityTutorialsSqlMembershipProvider` provider we could have cleared out all previously registered providers by adding a `<clear />` element immediately before our `<add>` element. This would clear out the `AspNetSqlMembershipProvider` from the list of registered providers, meaning that the `SecurityTutorialsSqlMembershipProvider` would be the only registered Membership provider. If we used this approach, then we would not need to mark the `SecurityTutorialsSqlMembershipProvider` as the default provider, since it would be the only registered Membership provider. For more information on using `<clear />`, see Using `<clear />` When Adding providers.

Note that the `SecurityTutorialsSqlMembershipProvider`'s `connectionStringName` setting references the just-added `SecurityTutorialsConnectionString` connection string name, and that its `applicationName` setting has been set to a value of SecurityTutorials. Additionally, the `requiresUniqueEmail` setting has been set to `true`. All other configuration options are identical to the values in `AspNetSqlMembershipProvider`. Feel free to make any configuration modifications here, if you wish. For example, you could tighten the password strength by requiring two non-alphanumeric characters instead of one, or by increasing the password length to eight characters instead of seven.

> **NOTE**
>
> Recall that the Membership framework allows for a single user store to be partitioned across multiple applications. The Membership provider's `applicationName` setting indicates what application the provider uses when working with the user store. It is important that you explicitly set a value for the `applicationName` configuration setting because if the `applicationName` is not explicitly set, it is assigned to the web application's virtual root path at runtime. This works fine as long as the application's virtual root path doesn't change, but if you move the application to a different path, the `applicationName` setting will change too. When this happens, the Membership provider will start working with a different application partition than was previously used. User accounts created prior to the move will reside in a different application partition and those users will no longer be able to log into the site. For a more in-depth discussion on this matter, see Always Set the `applicationName` Property When Configuring ASP.NET 2.0 Membership and Other providers.

Summary

At this point we have a database with the configured application services (`SecurityTutorials.mdf`) and have configured our web application so that the Membership framework uses the `SecurityTutorialsSqlMembershipProvider` provider we just registered. This registered provider is of type `SqlMembershipProvider` and has its `connectionStringName` set to the appropriate connection string (`SecurityTutorialsConnectionString`) and its `applicationName` value explicitly set.

We are now ready to use the Membership framework from our application. In the next tutorial we will examine how to create new user accounts. Following that we will explore authenticating users, performing user-based authorization, and storing additional user-related information in the database.

Happy Programming!

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will explore using the Membership framework (via the SqlMembershipProvider) to create new user accounts. We will see how to create new users programmatically and through ASP.NET's built-in CreateUserWizard control.

Introduction

In the preceding tutorial we installed the application services schema in a database, which added the tables, views, and stored procedures needed by the `SqlMembershipProvider` and `SqlRoleProvider`. This created the infrastructure we will need for the remainder of the tutorials in this series. In this tutorial we will explore using the Membership framework (via the `SqlMembershipProvider`) to create new user accounts. We will see how to create new users programmatically and through ASP.NET's built-in CreateUserWizard control.

In addition to learning how to create new user accounts, we will also need to update the demo website we first created in the *An Overview of Forms Authentication* tutorial and then enhanced in the *Forms Authentication Configuration and Advanced Topics* tutorial. Our demo web application has a login page that validates users' credentials against hard-coded username/password pairs. Moreover, `Global.asax` includes code that creates custom `IPrincipal` and `IIdentity` objects for authenticated users. We will update the login page to validate users' credentials against the Membership framework and remove the custom principal and identity logic.

Let's get started!

The Forms Authentication and Membership Checklist

Before we begin working with the Membership framework, let's take a moment to review the important steps we have taken to reach this point. When using the Membership framework with the `SqlMembershipProvider` in a forms-based authentication scenario, the following steps need to be performed prior to implementing Membership functionality in your web application:

1. **Enable forms-based authentication.** As we discussed in *An Overview of Forms Authentication*, forms authentication is enabled by editing `Web.config` and setting the `<authentication>` element's `mode` attribute to `Forms`. With forms authentication enabled, each incoming request is examined for a *forms authentication ticket*, which, if present, identifies the requestor.
2. **Add the application services schema to the appropriate database.** When using the `SqlMembershipProvider` we need to install the application services schema to a database. Usually this schema is added to the same database that holds the application's data model. The *Creating the Membership Schema in SQL Server* tutorial looked at using the `aspnet_regsql.exe` tool to accomplish this.
3. **Customize the Web Application's Settings to reference the database from step 2.** The *Creating the Membership Schema in SQL Server* tutorial showed two ways to configure the web application so that the `SqlMembershipProvider` would use the database selected in step 2: by modifying the `LocalSqlServer` connection string name; or by adding a new registered provider to the list of Membership framework providers and customizing that new provider to use the database from step 2.

When building a web application that uses the `SqlMembershipProvider` and forms-based authentication, you will

need to perform these three steps before using the `Membership` class or the ASP.NET Login Web controls. Since we already performed these steps in previous tutorials, we are ready to start using the Membership framework!

Step 1: Adding New ASP.NET Pages

In this tutorial and the next three we will be examining various Membership-related functions and capabilities. We will need a series of ASP.NET pages to implement the topics examined throughout these tutorials. Let's create those pages and then a site map file `(Web.sitemap)`.

Start by creating a new folder in the project named `Membership`. Next, add five new ASP.NET pages to the `Membership` folder, linking each page with the `Site.master` master page. Name the pages:

- `CreatingUserAccounts.aspx`
- `UserBasedAuthorization.aspx`
- `EnhancedCreateUserWizard.aspx`
- `AdditionalUserInfo.aspx`
- `Guestbook.aspx`

At this point your project's Solution Explorer should look similar to the screen shot shown in Figure 1.

Figure 1: Five New Pages Have Been Added to the `Membership` Folder (Click to view full-size image)

Each page should, at this point, have the two Content controls, one for each of the master page's ContentPlaceHolders: `MainContent` and `LoginContent`.

```
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent"
Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="LoginContent"
Runat="Server">
</asp:Content>
```

Recall that the `LoginContent` ContentPlaceHolder's default markup displays a link to log on or log off the site, depending on whether the user is authenticated. The presence of the `Content2` Content control, however, overrides the master page's default markup. As we discussed in *An Overview of Forms Authentication* tutorial, this is useful in pages where we do not want to display login-related options in the left column.

For these five pages, however, we want to show the master page's default markup for the `LoginContent` ContentPlaceHolder. Therefore, remove the declarative markup for the `Content2` Content control. After doing so,

each of the five page's markup should contain just one Content control.

Step 2: Creating the Site Map

All but the most trivial websites need to implement some form of a navigational user interface. The navigation user interface may be a simple list of links to the various sections of the site. Alternatively, these links may be arranged into menus or tree views. As page developers, creating the navigational user interface is only half of the story. We also need some means to define the site's logical structure in a maintainable and updateable fashion. As new pages are added or existing pages removed, we want to be able to update a single source - the site map - and have those modifications reflected across the site's navigational user interface.

These two tasks - defining the site map and implementing a navigational user interface based on the site map - are easy to accomplish thanks to the Site Map framework and the Navigation Web controls added in ASP.NET version 2.0. The Site Map framework allows for a developer to define a site map and then to access it through a programmatic API (the `SiteMap` class). The built-in Navigation Web controls include a Menu control, the TreeView control, and the SiteMapPath control.

Like the Membership and Roles frameworks, the Site Map framework is built atop the provider model. The job of the Site Map provider class is to generate the in-memory structure used by the `SiteMap` class from a persistent data store, such as an XML file or a database table. The .NET Framework ships with a default Site Map provider that reads the site map data from an XML file (`XmlSiteMapProvider`), and this is the provider we will be using in this tutorial. For some alternate Site Map provider implementations, refer to the Further Readings section at the end of this tutorial.

The default Site Map provider expects a properly-formatted XML file named `Web.sitemap` to exist the root directory. Since we are using this default provider, we need to add such a file and define the site map's structure in the appropriate XML format. To add the file, right-click on the project name in Solution Explorer and choose Add New Item. From the dialog box, opt to add a file of type Site Map named `Web.sitemap`.

Figure 2: Add a File Named `Web.sitemap` to the Project's Root Directory (Click to view full-size image)

The XML site map file defines the website's structure as a hierarchy. This hierarchical relationship is modeled in the XML file via the ancestry of the `<siteMapNode>` elements. The `Web.sitemap` must start with a `<siteMap>` parent node that has precisely one `<siteMapNode>` child. This top-level `<siteMapNode>` element represents the root of the hierarchy, and may have an arbitrary number of descendent nodes. Each `<siteMapNode>` element must include a `title` attribute and may optionally include `url` and `description` attributes, among others; each non-empty `url` attribute must be unique.

Enter the following XML into the `Web.sitemap` file:

```
<?xml version="1.0" encoding="utf-8" ?>
<siteMap xmlns="http://schemas.microsoft.com/AspNet/SiteMap-File-1.0">
 <siteMapNode url="~/Default.aspx" title="Home">
 <siteMapNode title="Membership">
 <siteMapNode url="~/Membership/CreatingUserAccounts.aspx" title="Creating User Accounts" />
 <siteMapNode url="~/Membership/UserBasedAuthorization.aspx" title="User-Based Authorization" />
 <siteMapNode url="~/Membership/Guestbook.aspx" title="Storing Additional User Information" />
 </siteMapNode>
 </siteMapNode>
</siteMap>
```

The above site map markup defines the hierarchy shown in Figure 3.

Figure 3: The Site Map Represents a Hierarchical Navigational Structure (Click to view full-size image)

Step 3: Updating the Master Page to Include a Navigational User Interface

ASP.NET includes a number of navigation-related Web controls for designing a user interface. These include the Menu, TreeView, and the SiteMapPath controls. The Menu and TreeView controls render the site map structure in a menu or a tree, respectively, whereas the SiteMapPath displays a breadcrumb that shows the current node being visited as well as its ancestors. The site map data can be bound to other data Web controls using the SiteMapDataSource and can be accessed programmatically via the `SiteMap` class.

Since a thorough discussion of the Site Map framework and the Navigation controls is beyond the scope of this tutorial series, rather than spend time crafting our own navigational user interface let's instead borrow the one used in my *Working with Data in ASP.NET 2.0* tutorial series, which uses a Repeater control to display a two-deep bulleted list of navigation links, as shown in Figure 4.

Adding a Two-Level List of Links in the Left Column

To create this interface, add the following declarative markup to the `Site.master` master page's left column where the text TODO: Menu will go here... currently resides.

```
<ul>
 <li>
 <asp:HyperLink runat="server" ID="lnkHome" NavigateUrl="~/Default.aspx">Home</asp:HyperLink>
 </li>
 <asp:Repeater runat="server" ID="menu" DataSourceID="SiteMapDataSource1">
 <ItemTemplate>
 <li>
 <asp:HyperLink ID="lnkMenuItem" runat="server"
 NavigateUrl='<%# Eval("Url") %>'><%# Eval("Title") %></asp:HyperLink>
 <asp:Repeater ID="submenu" runat="server" DataSource="<%#
 CType(Container.DataItem, SiteMapNode).ChildNodes %>">
 <HeaderTemplate>
 <ul>
 </HeaderTemplate>
 <ItemTemplate>
 <li>
 <asp:HyperLink ID="lnkMenuItem"
 runat="server" NavigateUrl='<%#  Eval("Url") %>'><%# Eval("Title") %></asp:HyperLink>
 </li>
 </ItemTemplate>
 <FooterTemplate>
 </ul>
 </FooterTemplate>
 </asp:Repeater>
 </li>
 </ItemTemplate>
 </asp:Repeater>
</ul>
<asp:SiteMapDataSource ID="SiteMapDataSource1" runat="server" ShowStartingNode="false"/>
```

The above markup binds a Repeater control named `menu` to a SiteMapDataSource, which returns the site map hierarchy defined in `Web.sitemap`. Since the SiteMapDataSource control's `ShowStartingNode` property is set to False it starts returning the site map's hierarchy starting with the descendents of the Home node. The Repeater displays each of these nodes (currently just Membership) in an `<li>` element. Another, inner Repeater then displays the current node's children in a nested unordered list.

Figure 4 shows the above markup's rendered output with the site map structure we created in Step 2. The Repeater renders vanilla unordered list markup; the cascading style sheet rules defined in `Styles.css` are responsible for the aesthetically-pleasing layout. For a more detailed description of how the above markup works, refer to the Master Pages and Site Navigation tutorial.

Figure 4: The Navigational User Interface is Rendered Using Nested Unordered Lists (Click to view full-size image)

Adding Breadcrumb Navigation

In addition to the list of links in the left column, let's also have each page display a breadcrumb. A breadcrumb is a navigational user interface element that quickly shows users their current position within the site hierarchy. The SiteMapPath control uses the Site Map framework to determine the current page's location in the site map and then displays a breadcrumb based on this information.

Specifically, add a `<span>` element to the master page's header `<div>` element, and set the new `<span>` element's `class` attribute to breadcrumb. (The `Styles.css` class contains a rule for a breadcrumb class.) Next, add a SiteMapPath to this new `<span>` element.

```
<div id="header">
 <span class="title">User Account Tutorials</span><br />
 <span class="breadcrumb">
 <asp:SiteMapPath ID="SiteMapPath1" runat="server">
 </asp:SiteMapPath>
 </span>
</div>
```

Figure 5 shows the output of the SiteMapPath when visiting `~/Membership/CreatingUserAccounts.aspx`.

Home > Membership > Creating User Accounts

Figure 5: The Breadcrumb Displays the Current Page and its Ancestors in the Site Map (Click to view full-size image)

Step 4: Removing the Custom Principal and Identity Logic

In the *Forms Authentication Configuration and Advanced Topics* tutorial we saw how to associate custom principal and identity objects to the authenticated user. We accomplished this by creating an event handler in `Global.asax` for the application's `PostAuthenticateRequest` event, which fires after the `FormsAuthenticationModule` has authenticated the user. In this event handler we replaced the `GenericPrincipal` and `FormsIdentity` objects added by the `FormsAuthenticationModule` with the `CustomPrincipal` and `CustomIdentity` objects we created in that tutorial.

While custom principal and identity objects are useful in certain scenarios, in most cases the `GenericPrincipal` and `FormsIdentity` objects are sufficient. Consequently, I think it would be worthwhile to return to the default behavior. Make this change by either removing or commenting out the `PostAuthenticateRequest` event handler or by deleting the `Global.asax` file entirely.

> **NOTE**
> Once you've commented or removed the code in `Global.asax`, you will need to comment out the code in `Default.aspx's` code-behind class that casts the `User.Identity` property to a `CustomIdentity` instance.

Step 5: Programmatically Creating a New User

To create a new user account through the Membership framework use the `Membership` class's `CreateUser` method. This method has input parameters for the username, password, and other user-related fields. On invocation, it delegates the creation of the new user account to the configured Membership provider and then returns a `MembershipUser` object representing the just-created user account.

The `CreateUser` method has four overloads, each accepting a different number of input parameters:

- `CreateUser(username, password)`
- `CreateUser(username, password, email)`
- `CreateUser(username, password, email, passwordQuestion, passwordAnswer, isApproved, MembershipCreateStatus)`
- `CreateUser(username, password, email, passwordQuestion, passwordAnswer, isApproved, providerUserKey, MembershipCreateStatus)`

These four overloads differ on the amount of information that is collected. The first overload, for example,

requires just the username and password for the new user account, whereas the second one also requires the user's email address.

These overloads exist because the information needed to create a new user account depends on the Membership provider's configuration settings. In the *Creating the Membership Schema in SQL Server* tutorial we examined specifying Membership provider configuration settings in `Web.config`. Table 2 included a complete list of the configuration settings.

One such Membership provider configuration setting that impacts what `CreateUser` overloads may be used is the `requiresQuestionAndAnswer` setting. If `requiresQuestionAndAnswer` is set to `true` (the default), then when creating a new user account we must specify a security question and answer. This information is later used if the user needs to reset or change their password. Specifically, at that time they are shown the security question and they must enter the correct answer in order to reset or change their password. Consequently, if the `requiresQuestionAndAnswer` is set to `true` then calling either of the first two `CreateUser` overloads results in an exception because the security question and answer are missing. Since our application is currently configured to require a security question and answer, we will need to use one of the latter two overloads when creating user's programmatically.

To illustrate using the `CreateUser` method, let's create a user interface where we prompt the user for their name, password, email, and an answer to a pre-defined security question. Open the `CreatingUserAccounts.aspx` page in the `Membership` folder and add the following Web controls to the Content control:

- A TextBox named `Username`
- A TextBox named `Password`, whose `TextMode` property is set to `Password`
- A TextBox named `Email`
- A Label named `SecurityQuestion` with its `Text` property cleared out
- A TextBox named `SecurityAnswer`
- A Button named `CreateAccountButton` whose `Text` property is set to Create the User Account
- A Label control named `CreateAccountResults` with its `Text` property cleared out

At this point your screen should look similar to the screen shot shown in Figure 6.

Figure 6: Add the Various Web Controls to the `CreatingUserAccounts.aspx Page` (Click to view full-size image)

The `SecurityQuestion` Label and `SecurityAnswer` TextBox are intended to display a pre-defined security question and collect the user's answer. Note that both the security question and answer are stored on a user-by-user

basis, so it is possible to allow each user to define their own security question. However, for this example I have decided to use a universal security question, namely: What is your favorite color?

To implement this pre-defined security question, add a constant to the page's code-behind class named `passwordQuestion`, assigning it the security question. Then, in the `Page_Load` event handler, assign this constant to the `SecurityQuestion` Label's `Text` property:

```
Const passwordQuestion As String = "What is your favorite color"
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Not Page.IsPostBack Then
 SecurityQuestion.Text = passwordQuestion
 End If
End Sub
```

Next, create an event handler for the `CreateAccountButton'` s `Click` event and add the following code:

```
Protected Sub CreateAccountButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
CreateAccountButton.Click
 Dim createStatus As MembershipCreateStatus
 Dim newUser As MembershipUser = _
 Membership.CreateUser(Username.Text, Password.Text, _
 Email.Text, passwordQuestion, _
 SecurityAnswer.Text, True, _
 createStatus)
 Select Case createStatus
 Case MembershipCreateStatus.Success
 CreateAccountResults.Text = "The user account was successfully created!"
 Case MembershipCreateStatus.DuplicateUserName
 CreateAccountResults.Text = "There already exists a user with this username."
 Case MembershipCreateStatus.DuplicateEmail
 CreateAccountResults.Text = "There already exists a user with this email address."
 Case MembershipCreateStatus.InvalidEmail
 CreateAccountResults.Text = "There email address you provided in invalid."
 Case MembershipCreateStatus.InvalidAnswer
 CreateAccountResults.Text = "There security answer was invalid."
 Case MembershipCreateStatus.InvalidPassword
 CreateAccountResults.Text = "The password you provided is invalid. It must be seven characters long and
have at least one non-alphanumeric character."
 Case Else
 CreateAccountResults.Text = "There was an unknown error; the user account was NOT created."
 End Select
End Sub
```

The `Click` event handler starts by defining a variable named `createStatus` of type `MembershipCreateStatus`. `MembershipCreateStatus` is an enumeration that indicates the status of the `CreateUser` operation. For example, if the user account is created successfully, the resulting `MembershipCreateStatus` instance will be set to a value of `Success;` on the other hand, if the operation fails because there already exists a user with the same username, it will be set to a value of `DuplicateUserName`. In the `CreateUser` overload we use, we need to pass a `MembershipCreateStatus` instance into the method. This parameter is set to the appropriate value within the `CreateUser` method, and we can examine its value after the method call to determine whether the user account was successfully created.

After calling `CreateUser`, passing in `createStatus`, a `Select Case` statement is used to output an appropriate message depending on the value assigned to `createStatus`. Figures 7 shows the output when a new user has successfully been created. Figures 8 and 9 show the output when the user account is not created. In Figure 8, the visitor entered a five-letter password, which does not meet the password strength requirements spelled out in the Membership provider's configuration settings. In Figure 9, the visitor is attempting to create a user account with an existing username (the one created in Figure 7).

Figure 7: A New User Account is Successfully Created (Click to view full-size image)

Figure 8: The User Account is Not Created Because the Supplied Password is Too Weak (Click to view full-size image)

Figure 9: The User Account is Not Created Because the Username is Already in Use (Click to view full-size

image)

> **NOTE**
>
> You may be wondering how to determine success or failure when using one of the first two `CreateUser` method overloads, neither of which has a parameter of type `MembershipCreateStatus`. These first two overloads throw a `MembershipCreateUserException` exception in the face of a failure, which includes a `StatusCode` property of type `MembershipCreateStatus`.

After creating a few user accounts, verify that the accounts have been created by listing the contents of the `aspnet_Users` and `aspnet_Membership` tables in the `SecurityTutorials.mdf` database. As Figure 10 shows, I have added two users via the `CreatingUserAccounts.aspx` page: Tito and Bruce.

Figure 10: There are Two Users in the Membership User Store: Tito and Bruce (Click to view full-size image)

While the Membership user store now includes Bruce and Tito's account information, we have yet to implement functionality that allows for Bruce or Tito to log on to the site. Currently, `Login.aspx` validates the user's credentials against a hard-coded set of username/password pairs - it does *not* validate the supplied credentials against the Membership framework. For now seeing the new user accounts in the `aspnet_Users` and `aspnet_Membership` tables will have to suffice. In the next tutorial, *Validating User Credentials Against the Membership User Store*, we will update the login page to validate against the Membership store.

> **NOTE**
>
> If you do not see any users in your `SecurityTutorials.mdf` database, it may be because your web application is using the default Membership provider, `AspNetSqlMembershipProvider`, which uses the `ASPNETDB.mdf` database as its user store. To determine if this is the problem, click the Refresh button in the Solution Explorer. If a database named `ASPNETDB.mdf` has been added to the `App_Data` folder, this is the problem. Return to Step 4 of the *Creating the Membership Schema in SQL Server* tutorial for instructions on how to properly configure the Membership provider.

In most create user account scenarios, the visitor is presented with some interface to enter their username, password, email, and other essential information, at which point a new account is created. In this step we looked at building such an interface by hand and then saw how to use the `Membership.CreateUser` method to programmatically add the new user account based on the user's inputs. Our code, however, just created the new user account. It did not perform any follow up actions, like logging in the user to the site under the just-created user account, or sending a confirmation email to the user. These additional steps would require additional code in the Button's `Click` event handler.

ASP.NET ships with the CreateUserWizard control, which is designed to handle the user account creation process, from rendering a user interface for creating new user accounts, to creating the account in the Membership framework and performing post-account creation tasks, such as sending a confirmation email and logging the

just-created user into the site. Using the CreateUserWizard control is as simple as dragging the CreateUserWizard control from the Toolbox onto a page, and then setting a few properties. In most cases, you won't need to write a single line of code. We will explore this nifty control in detail in Step 6.

If new user accounts are only created through a typical Create Account web page, it is unlikely that you will ever need to write code that uses the `CreateUser` method, as the CreateUserWizard control will likely meet your needs. However, the `CreateUser` method is handy in scenarios where you need a highly customized Create Account user experience or when you need to programmatically create new user accounts through an alternative interface. For example, you might have a page that allows a user to upload an XML file that contains user information from some other application. The page might parses the contents of the uploaded XML file and create a new account for each user represented in the XML by calling the `CreateUser` method.

Step 6: Creating a New User with the CreateUserWizard Control

ASP.NET ships with a number of Login Web controls. These controls aid in many common user account- and login-related scenarios. The CreateUserWizard control is one such control that is designed to present a user interface for adding a new user account to the Membership framework.

Like many of the other Login-related Web controls, the CreateUserWizard can be used without writing a single line of code. It intuitively provides a user interface based on the Membership provider's configuration settings and internally calls the `Membership` class's `CreateUser` method after the user enters the necessary information and clicks the Create User button. The CreateUserWizard control is extremely customizable. There are a host of events that fire during various stages of the account creation process. We can create event handlers, as needed, to inject custom logic into the account creation workflow. Furthermore, the CreateUserWizard's appearance is very flexible. There are a number of properties that define the appearance of the default interface; if necessary, the control can be converted into a template or additional user registration steps may be added.

Let's start with a look at using the CreateUserWizard control's default interface and behavior. We'll then explore how to customize the appearance via the control's properties and events.

Examining the CreateUserWizard's Default Interface and Behavior

Return to the `CreatingUserAccounts.aspx` page in the `Membership` folder, switch to the Design or Split mode, and then add a CreateUserWizard control to the top of the page. The CreateUserWizard control is filed under the Toolbox's Login controls section. After adding the control, set its `ID` property to `RegisterUser`. As the screen shot in Figure 11 shows, the CreateUserWizard renders an interface with textboxes for the new user's username, password, email address, and security question and answer.

Figure 11: The CreateUserWizard Control Renders a Generic Create User Interface (Click to view full-size image)

Let's take a moment to compare the default user interface generated by the CreateUserWizard control with the interface we created in Step 5. For starters, the CreateUserWizard control allows the visitor to specify both the security question and answer, whereas our manually-created interface used a pre-defined security question. The CreateUserWizard control's interface also includes validation controls, whereas we had yet to implement validation on our interface's form fields. And the CreateUserWizard control interface includes a Confirm Password textbox (along with a CompareValidator to ensure that the text entered the Password and Compare Password textboxes are equal).

What's interesting is that the CreateUserWizard control consults the Membership provider's configuration settings when rendering its user interface. For example, the security question and answer textboxes are only displayed if `requiresQuestionAndAnswer` is set to True. Likewise, CreateUserWizard automatically adds a RegularExpressionValidator control to ensure that the password strength requirements are met, and sets its `ErrorMessage` and `ValidationExpression` properties based on the `minRequiredPasswordLength`, `minRequiredNonalphanumericCharacters`, and `passwordStrengthRegularExpression` configuration settings.

The CreateUserWizard control, as its name implies, is derived from the Wizard control. Wizard controls are designed to provide an interface for completing multi-step tasks. A Wizard control may have an arbitrary number of `WizardSteps`, each of which is a template that defines the HTML and Web controls for that step. The Wizard control initially displays the first `WizardStep`, along with navigation controls that permit the user to proceed from one step to the next, or to return to previous steps.

As the declarative markup in Figure 11 shows, the CreateUserWizard control's default interface includes two `WizardStep` s:

- `CreateUserWizardStep` ? renders the interface to collect information for creating the new user account. This is the step shown in Figure 11.
- `CompleteWizardStep` ? renders a message indicating that the account has successfully been created.

The CreateUserWizard's appearance and behavior can be modified by converting either of these steps to templates, or by adding your own `WizardStep` s. We will look at adding a `WizardStep` to the registration interface in the *Storing Additional User Information* tutorial.

Let's see the CreateUserWizard control in action. Visit the `CreatingUserAccounts.aspx` page through a browser. Start by entering some invalid values into the CreateUserWizard's interface. Try entering a password that doesn't conform to the password strength requirements, or leaving the User Name textbox empty. The CreateUserWizard will display an appropriate error message. Figure 12 shows the output when attempting to create a user with an insufficiently strong password.

Figure 12: The CreateUserWizard Automatically Injects Validation Controls (Click to view full-size image)

Next, enter appropriate values into the CreateUserWizard and click the Create User button. Assuming the required fields have been entered and the password's strength is sufficient, the CreateUserWizard will create a new user account through the Membership framework and then display the `CompleteWizardStep`'s interface (see Figure 13). Behind the scenes, the CreateUserWizard calls the `Membership.CreateUser` method, just like we did in Step 5.

Figure 13: A New User Account has Successfully Been Created (Click to view full-size image)

> **NOTE**
>
> As Figure 13 shows, the `CompleteWizardStep`'s interface includes a Continue button. However, at this point clicking it just performs a postback, leaving the visitor on the same page. In the Customizing the CreateUserWizard's Appearance and Behavior Through Its Properties section we will look at how you can have this button send the visitor to `Default.aspx` (or some other page).

After creating a new user account, return to Visual Studio and examine the `aspnet_Users` and `aspnet_Membership` tables like we did in Figure 10 to verify that the account was successfully created.

Customizing the CreateUserWizard's Behavior and Appearance Through Its Properties

The CreateUserWizard can be customized in a variety of ways, through properties, `WizardStep` s, and event handlers. In this section we will look at how to customize the control's appearance through its properties; the next section looks at extending the control's behavior through event handlers.

Virtually all of the text displayed in the CreateUserWizard control's default user interface can be customized through its plethora of properties. For example, the User Name, Password, Confirm Password, E-mail, Security Question, and Security Answer labels displayed to the left of the textboxes can be customized by the `UserNameLabelText`, `PasswordLabelText`, `ConfirmPasswordLabelText`, `EmailLabelText`, `QuestionLabelText`, and `AnswerLabelText` properties, respectively. Likewise, there are properties for specifying the text for the Create User and Continue buttons in the `CreateUserWizardStep` and `CompleteWizardStep`, as well as if these buttons are rendered as Buttons, LinkButtons, or ImageButtons.

The colors, borders, fonts, and other visual elements are configurable through a host of style properties. The CreateUserWizard control itself has the common Web control style properties - `BackColor`, `BorderStyle`, `CssClass`, `Font`, and so on - and there are a number of style properties for defining the appearance for particular sections of the CreateUserWizard's interface. The `TextBoxStyle` property, for instance, defines the styles for the textboxes in the `CreateUserWizardStep`, while the `TitleTextStyle` property defines the style for the title (Sign Up for Your New Account).

In addition to the appearance-related properties, there are a number of properties that affect the CreateUserWizard control's behavior. The `DisplayCancelButton` property, if set to True, displays a Cancel button next to the Create User button (the default value is False). If you display the Cancel button, be sure to also set the `CancelDestinationPageUrl` property, which specifies the page the user is sent to after clicking Cancel. As noted in the previous section, the Continue button in the `CompleteWizardStep`'s interface causes a postback, but leaves the visitor on the same page. To send the visitor to some other page after clicking the Continue button, simply specify the URL in the `ContinueDestinationPageUrl` property.

Let's update the `RegisterUser` CreateUserWizard control to show a Cancel button and to send the visitor to `Default.aspx` when the Cancel or Continue buttons are clicked. To accomplish this, set the `DisplayCancelButton` property to True and both the `CancelDestinationPageUrl` and `ContinueDestinationPageUrl` properties to ~/Default.aspx. Figure 14 shows the updated CreateUserWizard when viewed through a browser.

Figure 14: The `CreateUserWizardStep` Includes a Cancel Button (Click to view full-size image)

When a visitor enters a username, password, email address, and security question and answer and clicks Create User, a new user account is created and the visitor is logged in as that newly created user. Assuming that the person visiting the page is creating a new account for themselves, this is likely the desired behavior. However, you may want to allow Administrators to add new user accounts. In doing so, the user account would be created, but the Administrator would remain logged in as an Administrator (and not as the newly created account). This behavior can be modified through the Boolean `LoginCreatedUser` property.

User accounts in the Membership framework contain an approved flag; users who are not approved are unable to log into the site. By default, a newly created account is marked as approved, allowing the user to log into the site immediately. It is possible, however, to have new user accounts marked as unapproved. Perhaps you want an Administrator to manually approve new users before they can log in; or maybe you want to verify that the email address entered at signup is valid before permitting a user to log on. Whatever the case may be, you can have the newly created user account marked as unapproved by setting the CreateUserWizard control's `DisableCreatedUser` property to True (the default is False).

Other behavior-related properties of note include `AutoGeneratePassword` and `MailDefinition`. If the `AutoGeneratePassword` property is set to True, the `CreateUserWizardStep` does not display the Password and Confirm Password textboxes; instead, the newly-created user's password is automatically generated using the `Membership` class's `GeneratePassword` method. The `GeneratePassword` method constructs a password of a specified length and with a sufficient number of non-alphanumeric characters to satisfy the configured password strength requirements.

The `MailDefinition` property is useful if you want to send an email to the email address specified during the account creation process. The `MailDefinition` property includes a series of subproperties for defining information about the constructed email message. These subproperties include options like `Subject`, `Priority`, `IsBodyHtml`, `From`, `CC`, and `BodyFileName`. The `BodyFileName` property points to a text or HTML file that contains the body for the email message. The body supports two pre-defined placeholders: `<%UserName%>` and `<%Password%>`. These placeholders, if present in the `BodyFileName` file, will be replaced with the just-created user's name and password.

> **NOTE**
>
> The `CreateUserWizard` control's `MailDefinition` property just specifies details about the email message that is sent when a new account is created. It does not include any details on how the email message is actually sent (that is, whether an SMTP server or mail drop directory is used, any authentication information, and so on). These low-level details need to be defined in the `<system.net>` section in `Web.config`. For more information on these configuration settings and on sending email from ASP.NET 2.0 in general, refer to the FAQs at SystemNetMail.com and my article, Sending Email in ASP.NET 2.0.

Extending the CreateUserWizard's Behavior Using Event Handlers

The CreateUserWizard control raises a number of events during its workflow. For example, after a visitor enters their username, password, and other pertinent information and clicks the Create User button, the CreateUserWizard control raises its `CreatingUser` event. If there is a problem during the create process, the `CreateUserError` event is fired; however, if the user is successfully created, then the `CreatedUser` event is raised. There are additional CreateUserWizard control events that get raised, but these are the three most germane ones.

In certain scenarios we may want to tap into the CreateUserWizard workflow, which we can do by creating an event handler for the appropriate event. To illustrate this, let's enhance the `RegisterUser` CreateUserWizard control to include some custom validation on the username and password. In particular, let's enhance our CreateUserWizard so that usernames cannot contain leading or trailing spaces and the username cannot appear anywhere in the password. In short, we want to prevent someone from creating a username like "Scott ", or having a username/password combination like Scott and Scott.1234 .

To accomplish this we will create an event handler for the `CreatingUser` event to perform our extra validation checks. If the supplied data is not valid we need to cancel the creation process. We also need to add a Label Web control to the page to display a message explaining that the username or password is invalid. Start by adding a Label control beneath the CreateUserWizard control, setting its `ID` property to `InvalidUserNameOrPasswordMessage` and its `ForeColor` property to `Red`. Clear out its `Text` property and set its `EnableViewState` and `Visible` properties to False.

```
<asp:Label runat="server"" id="InvalidUserNameOrPasswordMessage"
 Visible="false" ForeColor="Red" EnableViewState="false">
</asp:Label>
```

Next, create an event handler for the CreateUserWizard control's `CreatingUser` event. To create an event handler, select the control in the Designer and then go to the Properties window. From there, click on the lightning bolt icon and then double-click the appropriate event to create the event handler.

Add the following code to the `CreatingUser` event handler:

```
Protected Sub RegisterUser_CreatingUser(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.LoginCancelEventArgs) Handles RegisterUser.CreatingUser
 Dim trimmedUserName As String = RegisterUser.UserName.Trim()
 If RegisterUser.UserName.Length <> trimmedUserName.Length Then
 ' Show the error message
 InvalidUserNameOrPasswordMessage.Text = "The username cannot contain leading or trailing spaces."
 InvalidUserNameOrPasswordMessage.Visible = True
 ' Cancel the create user workflow
 e.Cancel = True
 Else
 ' Username is valid, make sure that the password does not contain the username
 If RegisterUser.Password.IndexOf(RegisterUser.UserName, StringComparison.OrdinalIgnoreCase) >= 0 Then
 ' Show the error message
 InvalidUserNameOrPasswordMessage.Text = "The username may not appear anywhere in the password."
 InvalidUserNameOrPasswordMessage.Visible = True
 ' Cancel the create user workflow
 e.Cancel = True
 End If
 End If
End Sub
```

Note that the username and password entered into the CreateUserWizard control are available through its `UserName` and `Password` properties, respectively. We use these properties in the above event handler to determine whether the supplied username contains leading or trailing spaces and whether the username is found within the password. If either of these conditions is met, an error message is displayed in the `InvalidUserNameOrPasswordMessage` Label and the event handler's `e.Cancel` property is set to `True`. If `e.Cancel` is set to `True`, the CreateUserWizard short-circuits its workflow, effectively cancelling the user account creation process.

Figure 15 shows a screen shot of `CreatingUserAccounts.aspx` when the user enters a username with leading spaces.

Figure 15: Usernames with Leading or Trailing Spaces are not Permitted (Click to view full-size image)

> **NOTE**
>
> We will see an example of using the CreateUserWizard control's `CreatedUser` event in the *Storing Additional User Information* tutorial.

Summary

The `Membership` class's `CreateUser` method creates a new user account in the Membership framework. It does so by delegating the call to the configured Membership provider. In the case of the `SqlMembershipProvider`, the `CreateUser` method adds a record to the `aspnet_Users` and `aspnet_Membership` database tables.

While new user accounts can be created programmatically (as we saw in Step 5), a faster and easier approach is to use the CreateUserWizard control. This control renders a multi-step user interface for collecting user information and creating a new user in the Membership framework. Underneath the covers, this control uses the same `Membership.CreateUser` method as examined in Step 5, but the control creates the user interface, validation controls, and responds to user account creation errors without having to write a lick of code.

At this point we have the functionality in place to create new user accounts. However, the login page still is validating against those hard-coded credentials we specified back in the second tutorial. In the next tutorial we will update `Login.aspx` to validate the user's supplied credentials against the Membership framework.

Happy Programming!

Validating User Credentials Against the Membership User Store (VB)

2/20/2020 • 25 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> In this tutorial we will examine how to validate a user's credentials against the Membership user store using both programmatic means and the Login control. We will also look at how to customize the login control's appearance and behavior.

Introduction

In the preceding tutorial we looked at how to create a new user account in the Membership framework. We first looked at programmatically creating user accounts via the `Membership` class's `CreateUser` method, and then examined using the CreateUserWizard Web control. However, the login page currently validates the supplied credentials against a hard-coded list of username and password pairs. We need to update the login page's logic so that it validates credentials against the Membership framework's user store.

Much like with creating user accounts, credentials can be validated programmatically or declaratively. The Membership API includes a method for programmatically validating a user's credentials against the user store. And ASP.NET ships with the Login Web control, which renders a user interface with textboxes for the username and password and a button to log in.

In this tutorial we will examine how to validate a user's credentials against the Membership user store using both programmatic means and the Login control. We will also look at how to customize the login control's appearance and behavior. Let's get started!

Step 1: Validating Credentials Against the Membership User Store

For web sites that use forms authentication, a user logs on to the website by visiting a login page and entering their credentials. These credentials are then compared against the user store. If they are valid, then the user is granted a forms authentication ticket, which is a security token that indicates the identity and authenticity of the visitor.

To validate a user against the Membership framework, use the `Membership` class's `ValidateUser` method. The `ValidateUser` method takes in two input parameters - `username` and `password` - and returns a Boolean value indicating whether the credentials were valid. Like with the `CreateUser` method we examined in the previous tutorial, the `ValidateUser` method delegates the actual validation to the configured Membership provider.

The `SqlMembershipProvider` validates the supplied credentials by obtaining the specified user's password via the `aspnet_Membership_GetPasswordWithFormat` stored procedure. Recall that the `SqlMembershipProvider` stores users' passwords using one of three formats: clear, encrypted, or hashed. The `aspnet_Membership_GetPasswordWithFormat` stored procedure returns the password in its raw format. For encrypted or hashed passwords, the `SqlMembershipProvider` transforms the `password` value passed into the `ValidateUser` method into its equivalent encrypted or hashed state and then compares it with what was returned from the database. If the password stored in the database matches the formatted password entered by the user, the credentials are valid.

Let's update our login page (~/`Login.aspx`) so that it validates the supplied credentials against the Membership

framework user store. We created this login page back in the *An Overview of Forms Authentication* tutorial, creating an interface with two TextBoxes for the username and password, a Remember Me checkbox, and a Login button (see Figure 1). The code validates the entered credentials against a hard-coded list of username and password pairs (Scott/password, Jisun/password, and Sam/password). In the *Forms Authentication Configuration and Advanced Topics* tutorial we updated the login page's code to store additional information in the forms authentication ticket's `UserData` property.

Figure 1: The Login Page's Interface Includes Two TextBoxes, a CheckBoxList, and a Button (Click to view full-size image)

The login page's user interface can remain unchanged, but we need to replace the Login button's `Click` event handler with code that validates the user against the Membership framework user store. Update the event handler so that its code appears as follows:

```
Protected Sub LoginButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
LoginButton.Click

 ' Validate the user against the Membership framework user store
 If Membership.ValidateUser(UserName.Text, Password.Text) Then
 ' Log the user into the site
 FormsAuthentication.RedirectFromLoginPage(UserName.Text, RememberMe.Checked)
 End If

 ' If we reach here, the user's credentials were invalid
 InvalidCredentialsMessage.Visible = True
End Sub
```

This code is remarkably simple. We start by calling the `Membership.ValidateUser` method, passing in the supplied username and password. If that method returns True, then the user is signed into the site via the `FormsAuthentication` class's RedirectFromLoginPage method. (As we discussed in the *An Overview of Forms Authentication* tutorial, the `FormsAuthentication.RedirectFromLoginPage` creates the forms authentication ticket and then redirects the user to the appropriate page.) If the credentials are invalid, however, the `InvalidCredentialsMessage` Label is displayed, informing the user that their username or password was incorrect.

That's all there is to it!

To test that the login page works as expected, attempt to login with one of the user accounts you created in the preceding tutorial. Or, if you have not yet created an account, go ahead and create one from the `~/Membership/CreatingUserAccounts.aspx` page.

> **NOTE**
>
> When the user enters her credentials and submits the login page form, the credentials, including her password, are transmitted over the Internet to the web server in *plain text*. That means any hacker sniffing the network traffic can see the username and password. To prevent this, it is essential to encrypt the network traffic by using Secure Socket Layers (SSL). This will ensure that the credentials (as well as the entire page's HTML markup) are encrypted from the moment they leave the browser until they are received by the web server.

How the Membership Framework Handles Invalid Login Attempts

When a visitor reaches the login page and submits their credentials, their browser makes an HTTP request to the login page. If the credentials are valid, the HTTP response includes the authentication ticket in a cookie. Therefore, a hacker attempting to break into your site could create a program that exhaustively sends HTTP requests to the login page with a valid username and a guess at the password. If the password guess is correct, the login page will return the authentication ticket cookie, at which point the program knows it has stumbled upon a valid username/password pair. Through brute force, such a program might be able to stumble upon a user's password, especially if the password is weak.

To prevent such brute force attacks, the Membership framework locks out a user if there are a certain number of unsuccessful login attempts within a certain period of time. The exact parameters are configurable through the following two Membership provider configuration settings:

- `maxInvalidPasswordAttempts` - specifies how many invalid password attempts are allowed for the user within the time period before the account is locked out. The default value is 5.
- `passwordAttemptWindow` - indicates the time period in minutes during which the specified number of invalid login attempts will cause the account to be locked out. The default value is 10.

If a user has been locked out, she cannot login until an administrator unlocks her account. When a user is locked out, the `ValidateUser` method will *always* return `False`, even if valid credentials are supplied. While this behavior lessens the likelihood that a hacker will break into your site through brute force methods, it can end up locking out a valid user who has simply forgotten her password or accidentally has the Caps Lock on or is having a bad typing day.

Unfortunately, there is no built-in tool for unlocking a user account. In order to unlock an account, you can modify the database directly - change the `IsLockedOut` field in the `aspnet_Membership` table for the appropriate user account - or create a web-based interface that lists locked out accounts with options to unlock them. We will examine creating administrative interfaces for accomplishing common user account- and role-related tasks in a future tutorial.

> **NOTE**
>
> One downside of the `ValidateUser` method is that when the supplied credentials are invalid, it does not provide any explanation as to why. The credentials may be invalid because there is no matching username/password pair in the user store, or because the user has not yet been approved, or because the user has been locked out. In Step 4 we will see how to show a more detailed message to the user when their login attempt fails.

Step 2: Collecting Credentials through the Login Web Control

The Login Web control renders a default user interface very similar to the one we created back in the *An*

Overview of Forms Authentication tutorial. Using the Login control saves us the work of having to create the interface to collect the visitor's credentials. Moreover, the Login control automatically signs in the user (assuming the submitted credentials are valid), thereby saving us from having to write any code.

Let's update `Login.aspx`, replacing the manually created interface and code with a Login control. Start by removing the existing markup and code in `Login.aspx`. You may delete it outright, or simply comment it out. To comment out declarative markup, surround it with the `<%--` and `--%>` delimiters. You can enter these delimiters manually, or, as Figure 2 shows, you may select the text to comment out and then click the Comment out the selected lines icon in the Toolbar. Similarly, you can use the Comment out the selected lines icon to comment out the selected code in the code-behind class.

Figure 2: Comment Out the Existing Declarative Markup and Source Code in Login.aspx (Click to view full-size image)

> **NOTE**
>
> The Comment out the selected lines icon is not available when viewing the declarative markup in Visual Studio 2005. If you are not using Visual Studio 2008 you will need to manually add the `<%--` and `--%>` delimiters.

Next, drag a Login control from the Toolbox on to the page and set its `ID` property to `myLogin`. At this point your screen should look similar to Figure 3. Note that the Login control's default interface includes TextBox controls for the username and password, a Remember me next time CheckBox, and a Log In Button. There are also `RequiredFieldValidator` controls for the two TextBoxes.

Figure 3: Add a Login Control to the Page (Click to view full-size image)

And we're done! When the Login control's Log In button is clicked, a postback will occur and the Login control will call the `Membership.ValidateUser` method, passing in the entered username and password. If the credentials are invalid, the Login control displays a message stating such. If, however, the credentials are valid, then the Login control creates the forms authentication ticket and redirects the user to the appropriate page.

The Login control uses four factors to determine the appropriate page to redirect the user to upon a successful login:

- Whether the Login control is on the login page as defined by `loginUrl` setting in the forms authentication configuration; this setting's default value is `Login.aspx`
- The presence of a `ReturnUrl` querystring parameter
- The value of the Login control's `DestinationUrl` property
- The `defaultUrl` value specified in the forms authentication configuration settings; this setting's default value is Default.aspx

Figure 4 depicts the how the Login control uses these four parameters to arrive at its appropriate page decision.

Figure 4: Add a Login Control to the Page (Click to view full-size image)

Take a moment to test out the Login control by visiting the site through a browser and logging in as an existing user in the Membership framework.

The Login control's rendered interface is highly configurable. There are a number of properties that influence its appearance; what's more, the Login control can be converted into a template for precise control over the layout the user interface elements. The remainder of this step examines how to customize the appearance and layout.

Customizing the Login Control's Appearance

The Login control's default property settings render a user interface with a title (Log In), TextBox and Label controls for the username and password inputs, a Remember me next time CheckBox, and a Log In button. The appearances of these elements are all configurable through the Login control's numerous properties. Furthermore, additional user interface elements - such as a link to a page to create a new user account - can be added by setting a property or two.

Let's spend a few moments to gussy up the appearance of our Login control. Since the `Login.aspx` page already has text at the top of the page that says Login, the Login control's title is superfluous. Therefore, clear out the `TitleText` property value in order to remove the Login control's title.

The User Name: and Password: Labels to the left of the two TextBox controls can be customized through the `UserNameLabelText` and `PasswordLabelText` properties, respectively. Let's change the User Name: Label to read Username:. The Label and TextBox styles are configurable through the `LabelStyle` and `TextBoxStyle` properties, respectively.

The Remember me next time CheckBox's Text property can be set through the Login control's `RememberMeText` property, and its default checked state is configurable through the `RememberMeSet` property (which defaults to False). Go ahead and set the `RememberMeSet` property to True so that the Remember me next time CheckBox will be checked by default.

The Login control offers two properties for adjusting the layout of its user interface controls. The `TextLayout` property indicates whether the Username: and Password: Labels appear to the left of their corresponding

TextBoxes (the default), or above them. The `Orientation` property indicates whether the username and password inputs are situated vertically (one above the other) or horizontally. I am going to leave these two properties set to their defaults, but I encourage you to try setting these two properties to their non-default values to see the resulting effect.

> **NOTE**
>
> In the next section, Configuring the Login Control's Layout, we will look at using templates to define the precise layout of the Layout control's user interface elements.

Wrap up the Login control's property settings by setting the `CreateUserText` and `CreateUserUrl` properties to Not registered yet? Create an account! and `~/Membership/CreatingUserAccounts.aspx`, respectively. This adds a hyperlink to the Login control's interface pointing to the page we created in the preceding tutorial. The Login control's `HelpPageText` and `HelpPageUrl` properties and `PasswordRecoveryText` and `PasswordRecoveryUrl` properties work in the same manner, rendering links to a help page and a password recovery page.

After making these property changes, your Login control's declarative markup and appearance should look similar to that shown in Figure 5.

Figure 5: The Login Control's Properties' Values Dictate Its Appearance (Click to view full-size image)

Configuring the Login Control's Layout

The Login Web control's default user interface lays out the interface in an HTML `<table>`. But what if we need finer control over the rendered output? Maybe we want to replace the `<table>` with a series of `<div>` tags. Or what if our application requires additional credentials for authentication? Many financial websites, for instance, require users to supply not only a username and password, but also a Personal Identification Number (PIN), or other identifying information. Whatever the reasons may be, it is possible to convert the Login control into a template, from which we can explicitly define the interface's declarative markup.

We need to do two things in order to update the Login control to collect additional credentials:

1. Update the Login control's interface to include Web control(s) to collect the additional credentials.
2. Override the Login control's internal authentication logic so that a user is only authenticated if their username

and password is valid and their additional credentials are valid, too.

To accomplish the first task, we need to convert the Login control into a template and add the necessary Web controls. As for the second task, the Login control's authentication logic can be superseded by creating an event handler for the control's `Authenticate` event.

Let's update the Login control so that it prompts users for their username, password, and email address and only authenticates the user if the email address supplied matches their email address on file. We first need to convert the Login control's interface to a template. From the Login control's Smart Tag, choose the Convert to template option.

Figure 6: Convert the Login Control to a Template (Click to view full-size image)

> **NOTE**
>
> To revert the Login control to its pre-template version, click the Reset link from the control's Smart Tag.

Converting the Login control to a template adds a `LayoutTemplate` to the control's declarative markup with HTML elements and Web controls defining the user interface. As Figure 7 shows, converting the control to a template removes a number of properties from the Properties window, such as `TitleText`, `CreateUserUrl`, and so forth, since these property values are ignored when using a template.

Figure 7: Fewer Properties are Available When the Login Control is Converted to a Template (Click to view full-size image)

The HTML markup in the `LayoutTemplate` may be modified as needed. Likewise, feel free to add any new Web controls to the template. However, it is important that Login control's core Web controls remain in the template and keep their assigned `ID` values. In particular, do not remove or rename the `UserName` or `Password` TextBoxes, the `RememberMe` CheckBox, the `LoginButton` Button, the `FailureText` Label, or the `RequiredFieldValidator` controls.

To collect the visitor's email address, we need to add a TextBox to the template. Add the following declarative markup between the table row (`<tr>`) that contains the `Password` TextBox and the table row that holds the Remember me next time CheckBox:

```
<tr>
 <td align="right">
 <asp:Label ID="EmailLabel" runat="server" AssociatedControlID="Email">Email:</asp:Label>
 </td>
 <td>
 <asp:TextBox ID="Email" runat="server"></asp:TextBox>
 <asp:RequiredFieldValidator ID="EmailRequired" runat="server"
 ControlToValidate="Email" ErrorMessage="Email is required."
 ToolTip="Email is required." ValidationGroup="myLogin">*</asp:RequiredFieldValidator>
 </td>
</tr>
```

After adding the `Email` TextBox, visit the page through a browser. As Figure 8 shows, the Login control's user interface now includes a third textbox.

Figure 8: The Login Control Now Includes a Textbox for the User's Email Address (Click to view full-size image)

At this point, the Login control is still using the `Membership.ValidateUser` method to validate the supplied credentials. Correspondingly, the value entered into the `Email` TextBox has no bearing on whether the user can log in. In Step 3 we will look at how to override the Login control's authentication logic so that the credentials are only considered valid if the username and password are valid and the supplied email address matches up with the email address on file.

Step 3: Modifying the Login Control's Authentication Logic

When a visitor supplies her credentials and clicks the Log In button, a postback ensues and the Login control progresses through its authentication workflow. The workflow starts by raising the `LoggingIn` event. Any event handlers associated with this event may cancel the log in operation by setting the `e.Cancel` property to `True`.

If the log in operation is not cancelled, the workflow progresses by raising the `Authenticate` event. If there is an event handler for the `Authenticate` event, then it is responsible for determining whether the supplied credentials are valid or not. If no event handler is specified, the Login control uses the `Membership.ValidateUser` method to determine the validity of the credentials.

If the supplied credentials are valid, then the forms authentication ticket is created, the `LoggedIn` event is raised, and the user is redirected to the appropriate page. If, however, the credentials are deemed invalid, then the `LoginError` event is raised and a message is displayed informing the user that their credentials were invalid. By default, on failure the Login control simply sets its `FailureText` Label control's Text property to a failure message (Your login attempt was not successful. Please try again). However, if the Login control's `FailureAction` property is set to `RedirectToLoginPage`, then the Login control issues a `Response.Redirect` to the login page appending the querystring parameter `loginfailure=1` (which causes the Login control to display the failure message).

Figure 9 offers a flow chart of the authentication workflow.

Figure 9: The Login Control's Authentication Workflow (Click to view full-size image)

> **NOTE**
> If you are wondering when you would use the `FailureAction`'s `RedirectToLogin` page option, consider the following scenario. Right now our `Site.master` master page currently has the text, Hello, stranger displayed in the left column when visited by an anonymous user, but imagine that we wanted to replace that text with a Login control. This would allow an anonymous user to log in from any page on the site, instead of requiring them to visit the login page directly. However, if a user was unable to log in via the Login control rendered by the master page, it might make sense to redirect them to the login page (`Login.aspx`) because that page likely includes additional instructions, links, and other help - such as links to create a new account or retrieve a lost password - that were not added to the master page.

Creating the `Authenticate` Event Handler

In order to plug in our custom authentication logic, we need to create an event handler for the Login control's `Authenticate` event. Creating an event handler for the `Authenticate` event will generate the following event handler definition:

```
Protected Sub myLogin_Authenticate(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.AuthenticateEventArgs) Handles myLogin.Authenticate

End Sub
```

As you can see, the `Authenticate` event handler is passed an object of type `AuthenticateEventArgs` as its second input parameter. The `AuthenticateEventArgs` class contains a Boolean property named `Authenticated` that is used to specify whether the supplied credentials are valid. Our task, then, is to write code here that determines whether the supplied credentials are valid or not, and to set the `e.Authenticate` property accordingly.

Determining and Validating the Supplied Credentials

Use the Login control's `UserName` and `Password` properties to determine the username and password credentials

entered by the user. In order to determine the values entered into any additional Web controls (such as the `Email` TextBox we added in the previous step), use `LoginControlID.FindControl` ("*`controlID`*") to obtain a programmatic reference to the Web control in the template whose `ID` property is equal to *`controlID`*. For example, to get a reference to the `Email` TextBox, use the following code:

```
Dim EmailTextBox As TextBox = CType(myLogin.FindControl("Email"), TextBox)
```

In order to validate the user's credentials we need to do two things:

1. Ensure that the provided username and password are valid
2. Ensure that email address entered matches the email address on file for the user attempting to log in

To accomplish the first check we can simply use the `Membership.ValidateUser` method like we saw in Step 1. For the second check, we need to determine the user's email address so that we can compare it to the email address they entered into the TextBox control. To get information about a particular user, use the `Membership` class's `GetUser` method.

The `GetUser` method has a number of overloads. If used without passing in any parameters, it returns information about the currently logged in user. To get information about a particular user, call `GetUser` passing in their username. Either way, `GetUser` returns a `MembershipUser` object, which has properties like `UserName`, `Email`, `IsApproved`, `IsOnline`, and so on.

The following code implements these two checks. If both pass, then `e.Authenticate` is set to `True`, otherwise it is assigned `False`.

```
Protected Sub myLogin_Authenticate(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.AuthenticateEventArgs) Handles myLogin.Authenticate

 ' Get the email address entered
 Dim EmailTextBox As TextBox = CType(myLogin.FindControl("Email"), TextBox)
 Dim email As String = EmailTextBox.Text.Trim()

 ' Verify that the username/password pair is valid
 If Membership.ValidateUser(myLogin.UserName, myLogin.Password) Then

 ' Username/password are valid, check email
 Dim usrInfo As MembershipUser = Membership.GetUser(myLogin.UserName)

 If usrInfo IsNot Nothing AndAlso String.Compare(usrInfo.Email, email, True) = 0 Then
 ' Email matches, the credentials are valid
 e.Authenticated = True
 Else
 ' Email address is invalid...
 e.Authenticated = False
 End If
 Else
 ' Username/password are not valid...
 e.Authenticated = False
 End If
End Sub
```

With this code in place, attempt to log in as a valid user, entering the correct username, password, and email address. Try it again, but this time purposefully use an incorrect email address (see Figure 10). Finally, try it a third time using a non-existent username. In the first case you should be successfully logged on to the site, but in the last two cases you should see the Login control's invalid credentials message.

Figure 10: Tito Cannot Log In When Supplying an Incorrect Email Address (Click to view full-size image)

> **NOTE**
>
> As discussed in the How the Membership Framework Handles Invalid Login Attempts section in Step 1, when the `Membership.ValidateUser` method is called and passed invalid credentials, it keeps track of the invalid login attempt and locks out the user if they exceed a certain threshold of invalid attempts within a specified time window. Since our custom authentication logic calls the `ValidateUser` method, an incorrect password for a valid username will increment the invalid login attempt counter, but this counter is not incremented in the case where the username and password are valid, but the email address is incorrect. Chances are, this behavior is suitable, since it's unlikely that a hacker will know the username and password, but have to use brute force techniques to determine the user's email address.

Step 4: Improving the Login Control's Invalid Credentials Message

When a user attempts to log on with invalid credentials, the Login control displays a message explaining that the login attempt was unsuccessful. In particular, the control displays the message specified by its `FailureText` property, which has a default value of Your login attempt was not successful. Please try again.

Recall that there are many reasons why a user's credentials may be invalid:

- The username may not exist
- The username exists, but the password is invalid
- The username and password are valid, but the user is not yet approved
- The username and password are valid, but the user is locked out (most likely because they exceeded the number of invalid login attempts within the specified time frame)

And there may be other reasons when using custom authentication logic. For example, with the code we wrote in Step 3, the username and password may be valid, but the email address may be incorrect.

Regardless of why the credentials are invalid, the Login control displays the same error message. This lack of feedback can be confusing for a user whose account has not yet been approved or who has been locked out. With a little bit of work, though, we can have the Login control display a more appropriate message.

Whenever a user attempts to login with invalid credentials the Login control raises its `LoginError` event. Go ahead and create an event handler for this event, and add the following code:

```
Protected Sub myLogin_LoginError(ByVal sender As Object, ByVal e As System.EventArgs) Handles
myLogin.LoginError

 ' Determine why the user could not login...
 myLogin.FailureText = "Your login attempt was not successful. Please try again."

 ' Does there exist a User account for this user?
 Dim usrInfo As MembershipUser = Membership.GetUser(myLogin.UserName)

 If usrInfo IsNot Nothing Then
 ' Is this user locked out?
 If usrInfo.IsLockedOut Then
 myLogin.FailureText = "Your account has been locked out because of too many invalid login attempts. Please
contact the administrator to have your account unlocked."
 ElseIf Not usrInfo.IsApproved Then
 myLogin.FailureText = "Your account has not yet been approved. You cannot login until an administrator has
approved your account."
 End If
 End If
End Sub
```

The above code starts by setting the Login control's `FailureText` property to the default value (Your login attempt was not successful. Please try again). It then checks to see if the username supplied maps to an existing user account. If so, it consults the resulting `MembershipUser` object's `IsLockedOut` and `IsApproved` properties to determine if the account has been locked out or has not yet been approved. In either case, the `FailureText` property is updated to a corresponding value.

To test this code, purposefully attempt to log in as an existing user, but use an incorrect password. Do this five times in a row within a 10 minute time frame and the account will be locked out. As Figure 11 shows, subsequent login attempts will always fail (even with the correct password), but will now display the more descriptive Your account has been locked out because of too many invalid login attempts. Please contact the administrator to have your account unlocked message.

Figure 11: Tito Performed Too Many Invalid Login Attempts and Has Been Locked Out (Click to view full-size image)

Summary

Prior this tutorial, our login page validated the supplied credentials against a hard-coded list of

username/password pairs. In this tutorial, we updated the page to validate credentials against the Membership framework. In Step 1 we looked at using the `Membership.ValidateUser` method programmatically. In Step 2 we replaced our manually created user interface and code with the Login control.

The Login control renders a standard login user interface and automatically validates the user's credentials against the Membership framework. Moreover, in the event of valid credentials, the Login control signs the user in via forms authentication. In short, a fully functional login user experience is available by simply dragging the Login control onto a page, no extra declarative markup or code necessary. What's more, the Login control is highly customizable, allowing for a fine degree of control over both the rendered user interface and authentication logic.

At this point visitors to our website can create a new user account and log into the site, but we have yet to look at restricting access to pages based on the authenticated user. Currently, any user, authenticated or anonymous, can view any page on our site. Along with controlling access to our site's pages on a user-by-user basis, we might have certain pages whose functionality depends on the user. The next tutorial looks at how to limit access and in-page functionality based on the logged in user.

Happy Programming!

User-Based Authorization (VB)

2/20/2020 • 33 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> In this tutorial we will look at limiting access to pages and restricting page-level functionality through a variety of techniques.

Introduction

Most web applications that offer user accounts do so in part to restrict certain visitors from accessing certain pages within the site. In most online messageboard sites, for example, all users - anonymous and authenticated - are able to view the messageboard's posts, but only authenticated users can visit the web page to create a new post. And there may be administrative pages that are only accessible to a particular user (or a particular set of users). Moreover, page-level functionality can differ on a user-by-user basis. When viewing a list of posts, authenticated users are shown an interface for rating each post, whereas this interface is not available to anonymous visitors.

ASP.NET makes it easy to define user-based authorization rules. With just a bit of markup in `Web.config`, specific web pages or entire directories can be locked down so that they are only accessible to a specified subset of users. Page-level functionality can be turned on or off based on the currently logged in user through programmatic and declarative means.

In this tutorial we will look at limiting access to pages and restricting page-level functionality through a variety of techniques. Let's get started!

A Look at the URL Authorization Workflow

As discussed in the *An Overview of Forms Authentication* tutorial, when the ASP.NET runtime processes a request for an ASP.NET resource the request raises a number of events during its lifecycle. *HTTP Modules* are managed classes whose code is executed in response to a particular event in the request lifecycle. ASP.NET ships with a number of HTTP Modules that perform essential tasks behind the scenes.

One such HTTP Module is `FormsAuthenticationModule`. As discussed in previous tutorials, the primary function of the `FormsAuthenticationModule` is to determine the identity of the current request. This is accomplished by inspecting the forms authentication ticket, which is either located in a cookie or embedded within the URL. This identification takes place during the `AuthenticateRequest` event.

Another important HTTP Module is the `UrlAuthorizationModule`, which is raised in response to the `AuthorizeRequest` event (which happens after the `AuthenticateRequest` event). The `UrlAuthorizationModule` examines configuration markup in `Web.config` to determine whether the current identity has authority to visit the specified page. This process is referred to as *URL authorization*.

We'll examine the syntax for the URL authorization rules in Step 1, but first let's look at what the `UrlAuthorizationModule` does depending on whether the request is authorized or not. If the `UrlAuthorizationModule` determines that the request is authorized, then it does nothing, and the request continues through its lifecycle. However, if the request is *not* authorized, then the `UrlAuthorizationModule` aborts the lifecycle and instructs the `Response` object to return an HTTP 401 Unauthorized status. When using forms authentication this HTTP 401 status is never returned to the client because if the `FormsAuthenticationModule`

detects an HTTP 401 status is modifies it to an HTTP 302 Redirect to the login page.

Figure 1 illustrates the workflow of the ASP.NET pipeline, the `FormsAuthenticationModule`, and the `UrlAuthorizationModule` when an unauthorized request arrives. In particular, Figure 1 shows a request by an anonymous visitor for `ProtectedPage.aspx`, which is a page that denies access to anonymous users. Since the visitor is anonymous, the `UrlAuthorizationModule` aborts the request and returns an HTTP 401 Unauthorized status. The `FormsAuthenticationModule` then converts the 401 status into a 302 Redirect to login page. After the user is authenticated via the login page, he is redirected to `ProtectedPage.aspx`. This time the `FormsAuthenticationModule` identifies the user based on his authentication ticket. Now that the visitor is authenticated, the `UrlAuthorizationModule` permits access to the page.

Figure 1: The Forms Authentication and URL Authorization Workflow (Click to view full-size image)

Figure 1 depicts the interaction that occurs when an anonymous visitor attempts to access a resource that is not available to anonymous users. In such a case, the anonymous visitor is redirected to the login page with the page she attempted to visit specified in the querystring. Once the user has successfully logged on, she will be automatically redirected back to the resource she was initially attempting to view.

When the unauthorized request is made by an anonymous user, this workflow is straightforward and is easy for the visitor to understand what has happened and why. But keep in mind that the `FormsAuthenticationModule` will redirect *any* unauthorized user to the login page, even if the request is made by an authenticated user. This can result in a confusing user experience if an authenticated user attempts to visit a page for which she lacks authority.

Imagine that our website had its URL authorization rules configured such that the ASP.NET page `OnlyTito.aspx` was accessibly only to Tito. Now, imagine that Sam visits the site, logs on, and then attempts to visit `OnlyTito.aspx`. The `UrlAuthorizationModule` will halt the request lifecycle and return an HTTP 401 Unauthorized status, which the `FormsAuthenticationModule` will detect and then redirect Sam to the login page. Since Sam has already logged in, though, she may wonder why she has been sent back to the login page. She might reason that her login credentials were lost somehow, or that she entered invalid credentials. If Sam reenters her credentials from the login page she will be logged on (again) and redirected to `OnlyTito.aspx`. The `UrlAuthorizationModule`

will detect that Sam cannot visit this page and she will be returned to the login page.

Figure 2 depicts this confusing workflow.

Figure 2: The Default Workflow Can Lead to a Confusing Cycle (Click to view full-size image)

The workflow illustrated in Figure 2 can quickly befuddle even the most computer savvy visitor. We will look at ways to prevent this confusing cycle in Step 2.

> **NOTE**
>
> ASP.NET uses two mechanisms to determine whether the current user can access a particular web page: URL authorization and file authorization. File authorization is implemented by the `FileAuthorizationModule`, which determines authority by consulting the requested file(s) ACLs. File authorization is most commonly used with Windows authentication because ACLs are permissions that apply to Windows accounts. When using forms authentication, all operating system- and file system-level requests are executed by the same Windows account, regardless of the user visiting the site. Since this tutorial series focuses on forms authentication, we will not be discussing file authorization.

The Scope of URL Authorization

The `UrlAuthorizationModule` is managed code that is part of the ASP.NET runtime. Prior to version 7 of Microsoft's Internet Information Services (IIS) web server, there was a distinct barrier between IIS's HTTP pipeline and the ASP.NET runtime's pipeline. In short, in IIS 6 and earlier, ASP.NET's `UrlAuthorizationModule` only executes when a request is delegated from IIS to the ASP.NET runtime. By default, IIS processes static content itself - like HTML pages and CSS, JavaScript, and image files - and only hands off requests to the ASP.NET runtime when a page with an extension of `.aspx`, `.asmx`, or `.ashx` is requested.

IIS 7, however, allows for integrated IIS and ASP.NET pipelines. With a few configuration settings you can setup IIS 7 to invoke the `UrlAuthorizationModule` for *all* requests, meaning that URL authorization rules can be defined for files of any type. Additionally, IIS 7 includes its own URL authorization engine. For more information on ASP.NET integration and IIS 7's native URL authorization functionality, see Understanding IIS7 URL Authorization. For a more in-depth look at ASP.NET and IIS 7 integration, pick up a copy of Shahram Khosravi's book,

Professional IIS 7 and ASP.NET Integrated Programming (ISBN: 978-0470152539).

In a nutshell, in versions prior to IIS 7, URL authorization rules are only applied to resources handled by the ASP.NET runtime. But with IIS 7 it is possible to use IIS's native URL authorization feature or to integrate ASP.NET's `UrlAuthorizationModule` into IIS's HTTP pipeline, thereby extending this functionality to all requests.

> **NOTE**
> There are some subtle yet important differences in how ASP.NET's `UrlAuthorizationModule` and IIS 7's URL authorization feature process the authorization rules. This tutorial does not examine IIS 7's URL authorization functionality or the differences in how it parses authorization rules compared to the `UrlAuthorizationModule`. For more information on these topics, refer to the IIS 7 documentation on MSDN or at www.iis.net.

Step 1: Defining URL Authorization Rules in `Web.config`

The `UrlAuthorizationModule` determines whether to grant or deny access to a requested resource for a particular identity based on the URL authorization rules defined in the application's configuration. The authorization rules are spelled out in the `<authorization>` element in the form of `<allow>` and `<deny>` child elements. Each `<allow>` and `<deny>` child element can specify:

- A particular user
- A comma-delimited list of users
- All anonymous users, denoted by a question mark (?)
- All users, denoted by an asterisk (*)

The following markup illustrates how to use the URL authorization rules to allow users Tito and Scott and deny all others:

```
<authorization>
 <allow users="Tito, Scott" />
 <deny users="*" />
</authorization>
```

The `<allow>` element defines what users are permitted - Tito and Scott - while the `<deny>` element instructs that *all* users are denied.

> **NOTE**
> The `<allow>` and `<deny>` elements can also specify authorization rules for roles. We will examine role-based authorization in a future tutorial.

The following setting grants access to anyone other than Sam (including anonymous visitors):

```
<authorization>
 <deny users="Sam" />
</authorization>
```

To allow only authenticated users, use the following configuration, which denies access to all anonymous users:

```
<authorization>
 <deny users="?" />
</authorization>
```

The authorization rules are defined within the `<system.web>` element in `Web.config` and apply to all of the ASP.NET resources in the web application. Oftentimes, an application has different authorization rules for different sections. For example, at an eCommerce site, all visitors may peruse the products, see product reviews, search the catalog, and so on. However, only authenticated users may reach the checkout or the pages to manage one's shipping history. Moreover, there may be portions of the site that are only accessible by select users, such as site administrators.

ASP.NET makes it easy to define different authorization rules for different files and folders in the site. The authorization rules specified in the root folder's `Web.config` file apply to all ASP.NET resources in the site. However, these default authorization settings can be overridden for a particular folder by adding a `Web.config` with an `<authorization>` section.

Let's update our website so that only authenticated users can visit the ASP.NET pages in the `Membership` folder. To accomplish this we need to add a `Web.config` file to the `Membership` folder and set its authorization settings to deny anonymous users. Right-click the `Membership` folder in the Solution Explorer, choose the Add New Item menu from the context menu, and add a new Web Configuration File named `Web.config`.

Figure 3: Add a `Web.config` File to the `Membership` Folder (Click to view full-size image)

At this point your project should contain two `Web.config` files: one in the root directory and one in the `Membership` folder.

Figure 4: Your Application Should Now Contain Two `Web.config` Files (Click to view full-size image)

Update the configuration file in the `Membership` folder so that it prohibits access to anonymous users.

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 <authorization>
 <deny users="?" />
 </authorization>
 </system.web>
</configuration>
```

That's all there is to it!

To test out this change, visit the homepage in a browser and make sure you are logged out. Since the default behavior of an ASP.NET application is to allow all visitors, and since we didn't make any authorization modifications to the root directory's `Web.config` file, we are able to visit the files in the root directory as an anonymous visitor.

Click on the Creating User Accounts link found in the left column. This will take you to the `~/Membership/CreatingUserAccounts.aspx`. Since the `Web.config` file in the `Membership` folder defines authorization rules to prohibit anonymous access, the `UrlAuthorizationModule` aborts the request and returns an HTTP 401 Unauthorized status. The `FormsAuthenticationModule` modifies this to a 302 Redirect status, sending us to the login page. Note that the page we were attempting to access (`CreatingUserAccounts.aspx`) is passed to the login page via the `ReturnUrl` querystring parameter.

Figure 5: Since the URL Authorization Rules Prohibit Anonymous Access, We are Redirected to the Login Page (Click to view full-size image)

Upon successfully logging in, we are redirected to the `CreatingUserAccounts.aspx` page. This time the `UrlAuthorizationModule` permits access to the page because we are no longer anonymous.

Applying URL Authorization Rules to a Specific Location

The authorization settings defined in the `<system.web>` section of `Web.config` apply to all of the ASP.NET resources in that directory and its subdirectories (until otherwise overridden by another `Web.config` file). In some cases, though, we may want all ASP.NET resources in a given directory to have a particular authorization configuration except for one or two specific pages. This can be achieved by adding a `<location>` element in `Web.config`, pointing it to the file whose authorization rules differ, and defining its unique authorization rules therein.

To illustrate using the `<location>` element to override the configuration settings for a specific resource, let's customize the authorization settings so that only Tito can visit `CreatingUserAccounts.aspx`. To accomplish this, add a `<location>` element to the `Membership` folder's `Web.config` file and update its markup so that it looks like the following:

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 <authorization>
 <deny users="?" />
 </authorization>
 </system.web>

 <location path="CreatingUserAccounts.aspx">
 <system.web>
 <authorization>
 <allow users="Tito" />
 <deny users="*" />
 </authorization>
 </system.web>
 </location>
</configuration>
```

The `<authorization>` element in `<system.web>` defines the default URL authorization rules for ASP.NET resources in the `Membership` folder and its subfolders. The `<location>` element allows us to override these rules for a particular resource. In the above markup the `<location>` element references the `CreatingUserAccounts.aspx` page and specifies its authorization rules such as to allow Tito, but deny everyone else.

To test out this authorization change, start by visiting the website as an anonymous user. If you attempt to visit any page in the `Membership` folder, such as `UserBasedAuthorization.aspx`, the `UrlAuthorizationModule` will deny the request and you will be redirected to the login page. After logging in as, say, Scott, you can visit any page in the `Membership` folder *except* for `CreatingUserAccounts.aspx`. Attempting to visit `CreatingUserAccounts.aspx` logged on as anyone but Tito will result in an unauthorized access attempt, redirecting you back to the login page.

> **NOTE**
> The `<location>` element must appear outside of the configuration's `<system.web>` element. You need to use a separate `<location>` element for each resource whose authorization settings you want to override.

A Look at How the `UrlAuthorizationModule` Uses the Authorization Rules to Grant or Deny Access

The `UrlAuthorizationModule` determines whether to authorize a particular identity for a particular URL by analyzing the URL authorization rules one at a time, starting from the first one and working its way down. As soon as a match is found, the user is granted or denied access, depending on if the match was found in an `<allow>` or `<deny>` element. **If no match is found, the user is granted access.** Consequently, if you want to restrict access, it is imperative that you use a `<deny>` element as the last element in the URL authorization configuration. **If you omit a `<deny>` element, all users will be granted access.**

To better understand the process used by the `UrlAuthorizationModule` to determine authority, consider the example URL authorization rules we looked at earlier in this step. The first rule is an `<allow>` element that allows access to Tito and Scott. The second rules is a `<deny>` element that denies access to everyone. If an anonymous user visits, the `UrlAuthorizationModule` starts by asking, Is anonymous either Scott or Tito? The answer, obviously, is No, so it proceeds to the second rule. Is anonymous in the set of everybody? Since the answer here is Yes, the `<deny>` rule is put in effect and the visitor is redirected to the login page. Similarly, if Jisun is visiting, the `UrlAuthorizationModule` starts by asking, Is Jisun either Scott or Tito? Since she is not, the

`UrlAuthorizationModule` proceeds to the second question, Is Jisun in the set of everybody? She is, so she, too, is denied access. Finally, if Tito visits, the first question posed by the `UrlAuthorizationModule` is an affirmative answer, so Tito is granted access.

Since the `UrlAuthorizationModule` processes the authorization rules from the top down, stopping at any match, it is important to have the more specific rules come before the less specific ones. That is, to define authorization rules that forbid Jisun and anonymous users, but allow all other authenticated users, you would start with the most specific rule - the one impacting Jisun - and then proceed to the less specific rules - those allowing all other authenticated users, but denying all anonymous users. The following URL authorization rules implements this policy by first denying Jisun, and then denying any anonymous user. Any authenticated user other than Jisun will be granted access because neither of these `<deny>` statements will match.

```
<authorization>
 <deny users="Jisun" />
 <deny users="?" />
</authorization>
```

Step 2: Fixing the Workflow for Unauthorized, Authenticated Users

As we discussed earlier in this tutorial in the A Look at the URL Authorization Workflow section, anytime an unauthorized request transpires, the `UrlAuthorizationModule` aborts the request and returns an HTTP 401 Unauthorized status. This 401 status is modified by the `FormsAuthenticationModule` into a 302 Redirect status that sends the user to the login page. This workflow occurs on any unauthorized request, even if the user is authenticated.

Returning an authenticated user to the login page is likely to confuse them since they have already logged into the system. With a little bit of work we can improve this workflow by redirecting authenticated users who make unauthorized requests to a page that explains that they have attempted to access a restricted page.

Start by creating a new ASP.NET page in the web application's root folder named `UnauthorizedAccess.aspx`; don't forget to associate this page with the `Site.master` master page. After creating this page, remove the Content control that references the `LoginContent` ContentPlaceHolder so that the master page's default content will be displayed. Next, add a message that explains the situation, namely that the user attempted to access a protected resource. After adding such a message, the `UnauthorizedAccess.aspx` page's declarative markup should look similar to the following:

```
<%@ Page Language="VB" MasterPageFile="~/Site.master" AutoEventWireup="false"
CodeFile="UnauthorizedAccess.aspx.cs" Inherits="UnauthorizedAccess"
Title="Untitled Page" %>

<asp:Content ID="Content1" ContentPlaceHolderID="MainContent"
Runat="Server">
 <h2>Unauthorized Access</h2>
 <p>
 You have attempted to access a page that you are not authorized to view.
 </p>
 <p>
 If you have any questions, please contact the site administrator.
 </p>
</asp:Content>
```

We now need to alter the workflow so that if an unauthorized request is performed by an authenticated user they are sent to the `UnauthorizedAccess.aspx` page instead of the login page. The logic that redirects unauthorized requests to the login page is buried within a private method of the `FormsAuthenticationModule` class, so we cannot customize this behavior. What we can do, however, is add our own logic to the login page

that redirects the user to `UnauthorizedAccess.aspx`, if needed.

When the `FormsAuthenticationModule` redirects an unauthorized visitor to the login page it appends the requested, unauthorized URL to the querystring with the name `ReturnUrl`. For example, if an unauthorized user attempted to visit `OnlyTito.aspx`, the `FormsAuthenticationModule` would redirect them to `Login.aspx?ReturnUrl=OnlyTito.aspx`. Therefore, if the login page is reached by an authenticated user with a querystring that includes the `ReturnUrl` parameter, then we know that this unauthenticated user just attempted to visit a page she is not authorized to view. In such a case, we want to redirect her to `UnauthorizedAccess.aspx`.

To accomplish this, add the following code to the login page's `Page_Load` event handler:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Not Page.IsPostBack Then
 If Request.IsAuthenticated AndAlso Not String.IsNullOrEmpty(Request.QueryString("ReturnUrl")) Then
 ' This is an unauthorized, authenticated request...
 Response.Redirect("~/UnauthorizedAccess.aspx")
 End If
 End If
End Sub
```

The above code redirects authenticated, unauthorized users to the `UnauthorizedAccess.aspx` page. To see this logic in action, visit the site as an anonymous visitor and click on the Creating User Accounts link in the left column. This will take you to the `~/Membership/CreatingUserAccounts.aspx` page, which in Step 1 we configured to only permit access to Tito. Since anonymous users are prohibited, the `FormsAuthenticationModule` redirects us back to the login page.

At this point we are anonymous, so `Request.IsAuthenticated` returns `False` and we are not redirected to `UnauthorizedAccess.aspx`. Instead, the login page is displayed. Log in as a user other than Tito, such as Bruce. After entering the appropriate credentials, the login page redirects us back to `~/Membership/CreatingUserAccounts.aspx`. However, since this page is only accessible to Tito, we are unauthorized to view it and are promptly returned to the login page. This time, however, `Request.IsAuthenticated` returns `True` (and the `ReturnUrl` querystring parameter exists), so we are redirected to the `UnauthorizedAccess.aspx` page.

Figure 6: Authenticated, Unauthorized Users are Redirected to `UnauthorizedAccess.aspx` (Click to view full-size image)

This customized workflow presents a more sensible and straightforward user experience by short circuiting the cycle depicted in Figure 2.

Step 3: Limiting Functionality Based on the Currently Logged In User

URL authorization makes it easy to specify coarse authorization rules. As we saw in Step 1, with URL authorization we can succinctly state what identities are permitted and which ones are denied from viewing a particular page or all pages in a folder. In certain scenarios, however, we may want to allow all users to visit a page, but limit the page's functionality based on the user visiting it.

Consider the case of an eCommerce website that allows authenticated visitors to review their products. When an anonymous user visits a product's page, they would see just the product information and would not be given the opportunity to leave a review. However, an authenticated user visiting the same page would see the reviewing interface. If the authenticated user had not yet reviewed this product, the interface would enable them to submit a review; otherwise it would show them their previously-submitted review. To take this scenario a step further, the product page might show additional information and offer extended features for those users that work for the eCommerce company. For example, the product page might list the inventory in stock and include options to edit the product's price and description when visited by an employee.

Such fine grain authorization rules can be implemented either declaratively or programmatically (or through some combination of the two). In the next section we will see how to implement fine grain authorization via the LoginView control. Following that, we will explore programmatic techniques. Before we can look at applying fine grain authorization rules, however, we first need to create a page whose functionality depends on the user visiting it.

Let's create a page that lists the files in a particular directory within a GridView. Along with listing each file's name, size, and other information, the GridView will include two columns of LinkButtons: one titled View and one titled Delete. If the View LinkButton is clicked, the contents of the selected file will be displayed; if the Delete LinkButton is clicked, the file will be deleted. Let's initially create this page such that its view and delete functionality is available to all users. In the Using the LoginView Control and Programmatically Limiting Functionality sections we will see how to enable or disable these features based on the user visiting the page.

> **NOTE**
>
> The ASP.NET page we are about to build uses a GridView control to display a list of files. Since this tutorial series focuses on forms authentication, authorization, user accounts, and roles, I do not want to spend too much time discussing the inner workings of the GridView control. While this tutorial provides specific step-by-step instructions for setting up this page, it does not delve into the details of why certain choices were made, or what effect particular properties have on the rendered output. For a thorough examination of the GridView control, consult my *Working with Data in ASP.NET 2.0* tutorial series.

Start by opening the `UserBasedAuthorization.aspx` file in the `Membership` folder and adding a GridView control to the page named `FilesGrid`. From the GridView's Smart Tag, click the Edit Columns link to launch the Fields dialog box. From here, uncheck the Auto-generate fields checkbox in the lower left corner. Next, add a Select button, a Delete button, and two BoundFields from the upper left corner (the Select and Delete buttons can be found under the CommandField type). Set the Select button's `SelectText` property to View and the first BoundField's `HeaderText` and `DataField` properties to Name. Set the second BoundField's `HeaderText` property to Size in Bytes, its `DataField` property to Length, its `DataFormatString` property to {0:N0} and its `HtmlEncode` property to False.

After configuring the GridView's columns, click OK to close the Fields dialog box. From the Properties window, set the GridView's `DataKeyNames` property to `FullName`. At this point the GridView's declarative markup should look like the following:

```
<asp:GridView ID="FilesGrid" DataKeyNames="FullName" runat="server" AutoGenerateColumns="False">
 <Columns>
 <asp:CommandField SelectText="View" ShowSelectButton="True"/>
 <asp:CommandField ShowDeleteButton="True" />
 <asp:BoundField DataField="Name" HeaderText="Name" />
 <asp:BoundField DataField="Length" DataFormatString="{0:N0}"
 HeaderText="Size in Bytes" HtmlEncode="False" />
 </Columns>
</asp:GridView>
```

With the GridView's markup created, we're ready to write the code that will retrieve the files in a particular directory and bind them to the GridView. Add the following code to the page's `Page_Load` event handler:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Not Page.IsPostBack Then
 Dim appPath As String = Request.PhysicalApplicationPath
 Dim dirInfo As New DirectoryInfo(appPath)

 Dim files() As FileInfo = dirInfo.GetFiles()

 FilesGrid.DataSource = files
 FilesGrid.DataBind()
 End If
End Sub
```

The above code uses the `DirectoryInfo` class to obtain a list of the files in the application's root folder. The `GetFiles()` method returns all of the files in the directory as an array of `FileInfo` objects, which is then bound to the GridView. The `FileInfo` object has an assortment of properties, such as `Name`, `Length`, and `IsReadOnly`, among others. As you can see from its declarative markup, the GridView displays just the `Name` and `Length` properties.

> **NOTE**
> The `DirectoryInfo` and `FileInfo` classes are found in the `System.IO` namespace. Therefore, you will either need to preface these class names with their namespace names or have the namespace imported into the class file (via `Imports System.IO`).

Take a moment to visit this page through a browser. It will display the list of files residing in the application's root directory. Clicking any of the View or Delete LinkButtons will cause a postback, but no action will occur because we've yet to create the necessary event handlers.

Figure 7: The GridView Lists the Files in the Web Application's Root Directory (Click to view full-size image)

We need a means to display the contents of the selected file. Return to Visual Studio and add a TextBox named `FileContents` above the GridView. Set its `TextMode` property to `MultiLine` and its `Columns` and `Rows` properties to 95% and 10, respectively.

```
<asp:TextBox ID="FileContents" runat="server" Rows="10"
TextMode="MultiLine" Width="95%"></asp:TextBox>
```

Next, create an event handler for the GridView's `SelectedIndexChanged` event and add the following code:

```
Protected Sub FilesGrid_SelectedIndexChanged(ByVal sender As Object, ByVal e As System.EventArgs) Handles
FilesGrid.SelectedIndexChanged
 ' Open the file and display it
 Dim fullFileName As String = FilesGrid.SelectedValue.ToString()
 Dim contents As String = File.ReadAllText(fullFileName)
 FileContents.Text = contents
End Sub
```

This code uses the GridView's `SelectedValue` property to determine the full file name of the selected file. Internally, the `DataKeys` collection is referenced in order to obtain the `SelectedValue`, so it is imperative that you set the GridView's `DataKeyNames` property to Name, as described earlier in this step. The `File` class is used to read the selected file's contents into a string, which is then assigned to the `FileContents` TextBox's `Text` property, thereby displaying the contents of the selected file on the page.

Figure 8: The Selected File's Contents are Displayed in the TextBox (Click to view full-size image)

> **NOTE**
>
> If you view the contents of a file that contains HTML markup, and then attempt to view or delete a file, you will receive an `HttpRequestValidationException` error. This occurs because on postback the TextBox's contents are sent back to the web server. By default, ASP.NET raises an `HttpRequestValidationException` error whenever potentially dangerous postback content, such as HTML markup, is detected. To disable this error from occurring, turn off request validation for the page by adding `ValidateRequest="false"` to the `@Page` directive. For more information on the benefits of request validation as well as what precautions you should take when disabling it, read Request Validation - Preventing Script Attacks.

Finally, add an event handler with the following code for the GridView's `RowDeleting` event:

```
Protected Sub FilesGrid_RowDeleting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs)Handles FilesGrid.RowDeleting
 Dim fullFileName As String = FilesGrid.DataKeys(e.RowIndex).Value.ToString()
 FileContents.Text = String.Format("You have opted to delete {0}.", fullFileName)

 ' To actually delete the file, uncomment the following line
 ' File.Delete(fullFileName)
End Sub
```

The code simply displays the full name of the file to delete in the `FileContents` TextBox *without* actually deleting the file.

Figure 9: Clicking the Delete Button Does Not Actually Delete the File (Click to view full-size image)

In Step 1 we configured the URL authorization rules to prohibit anonymous users from viewing the pages in the `Membership` folder. In order to better exhibit fine grain authentication, let's allow anonymous users to visit the `UserBasedAuthorization.aspx` page, but with limited functionality. To open this page up to be accessed by all users, add the following `<location>` element to the `Web.config` file in the `Membership` folder:

```
<location path="UserBasedAuthorization.aspx">
 <system.web>
 <authorization>
 <allow users="*" />
 </authorization>
 </system.web>
</location>
```

After adding this `<location>` element, test the new URL authorization rules by logging out of the site. As an anonymous user you should be permitted to visit the `UserBasedAuthorization.aspx` page.

Currently, any authenticated or anonymous user can visit the `UserBasedAuthorization.aspx` page and view or delete files. Let's make it so that only authenticated users can view contents of a file and only Tito can delete a file. Such fine grain authorization rules can be applied declaratively, programmatically, or through a combination of both methods. Let's use the declarative approach to limit who can view the contents of a file; we'll use the programmatic approach to limit who can delete a file.

Using the LoginView Control

As we've seen in past tutorials, the LoginView control is useful for displaying different interfaces for authenticated and anonymous users, and offers an easy way to hide functionality that is not accessible to anonymous users. Since anonymous users cannot view or delete files, we only need to show the `FileContents` TextBox when the page is visited by an authenticated user. To achieve this, add a LoginView control to the page, name it `LoginViewForFileContentsTextBox`, and move the `FileContents` TextBox's declarative markup into the LoginView control's `LoggedInTemplate`.

```
<asp:LoginView ID=" LoginViewForFileContentsTextBox " runat="server">
 <LoggedInTemplate>
 <p>
 <asp:TextBox ID="FileContents" runat="server" Rows="10"
 TextMode="MultiLine" Width="95%"></asp:TextBox>
 </p>
 </LoggedInTemplate>
</asp:LoginView>
```

The Web controls in the LoginView's templates are no longer directly accessible from the code-behind class. For example, the `FilesGrid` GridView's `SelectedIndexChanged` and `RowDeleting` event handlers currently reference the `FileContents` TextBox control with code like:

```
FileContents.Text = text
```

However, this code is no longer valid. By moving the `FileContents` TextBox into the `LoggedInTemplate` the TextBox cannot be directly accessed. Instead, we must use the `FindControl("controlId")` method to programmatically reference the control. Update the `FilesGrid` event handlers to reference the TextBox like so:

```
Dim FileContentsTextBox As TextBox =
CType(LoginViewForFileContentsTextBox.FindControl("FileContents"),TextBox)
FileContentsTextBox.Text = text
```

After moving the TextBox to the LoginView's `LoggedInTemplate` and updating the page's code to reference the TextBox using the `FindControl("controlId")` pattern, visit the page as an anonymous user. As Figure 10 shows, the `FileContents` TextBox is not displayed. However, the View LinkButton is still displayed.

Figure 10: The LoginView Control Only Renders the `FileContents` TextBox for Authenticated Users (Click to view full-size image)

One way to hide the View button for anonymous users is to convert the GridView field into a TemplateField. This will generate a template that contains the declarative markup for the View LinkButton. We can then add a LoginView control to the TemplateField and place the LinkButton within the LoginView's `LoggedInTemplate`, thereby hiding the View button from anonymous visitors. To accomplish this, click on the Edit Columns link from the GridView's Smart Tag to launch the Fields dialog box. Next, select the Select button from the list in the lower left corner and then click the Convert this field to a TemplateField link. Doing so will modify the field's declarative markup from:

```
<asp:CommandField SelectText="View" ShowSelectButton="True"/>
```

To:

```
<asp:TemplateField ShowHeader="False">
 <ItemTemplate>
 <asp:LinkButton ID="LinkButton1" runat="server" CausesValidation="False"
 CommandName="Select" Text="View"></asp:LinkButton>
 </ItemTemplate>
</asp:TemplateField>
```

At this point, we can add a LoginView to the TemplateField. The following markup displays the View LinkButton only for authenticated users.

```
<asp:TemplateField ShowHeader="False">
 <ItemTemplate>
 <asp:LoginView ID="LoginView1" runat="server">
 <LoggedInTemplate>
 <asp:LinkButton ID="LinkButton1" runat="server" CausesValidation="False"
 CommandName="Select" Text="View"></asp:LinkButton>
 </LoggedInTemplate>
 </asp:LoginView>
 </ItemTemplate>
</asp:TemplateField>
```

As Figure 11 shows, the end result is not that pretty as the View column is still displayed even though the View LinkButtons within the column are hidden. We will look at how to hide the entire GridView column (and not just the LinkButton) in the next section.

Figure 11: The LoginView Control Hides the View LinkButtons for Anonymous Visitors (Click to view full-size image)

Programmatically Limiting Functionality

In some circumstances, declarative techniques are insufficient for limiting functionality to a page. For example, the availability of certain page functionality may be dependent on criteria beyond whether the user visiting the page is anonymous or authenticated. In such cases, the various user interface elements can be displayed or hidden through programmatic means.

In order to limit the functionality programmatically, we need to perform two tasks:

1. Determine whether the user visiting the page can access the functionality, and
2. Programmatically modify the user interface based on whether the user has access to the functionality in question.

To demonstrate the application of these two tasks, let's only allow Tito to delete files from the GridView. Our first task, then, is to determine whether it is Tito visiting the page. Once that has been determined, we need to hide (or show) the GridView's Delete column. The GridView's columns are accessible through its `Columns` property; a column is only rendered if its `Visible` property is set to `True` (the default).

Add the following code to the `Page_Load` event handler prior to binding the data to the GridView:

```
' Is this Tito visiting the page?
Dim userName As String = User.Identity.Name
If String.Compare(userName, "Tito", True) = 0 Then
 ' This is Tito, SHOW the Delete column
 FilesGrid.Columns(1).Visible = True
Else
 ' This is NOT Tito, HIDE the Delete column
 FilesGrid.Columns(1).Visible = False
End If
```

As we discussed in the *An Overview of Forms Authentication* tutorial, `User.Identity.Name` returns the identity's

name. This corresponds to the username entered in the Login control. If it is Tito visiting the page, the GridView's second column's `Visible` property is set to `True`; otherwise, it is set to `False`. The net result is that when someone other than Tito visits the page, either another authenticated user or an anonymous user, the Delete column is not rendered (see Figure 12); however, when Tito visits the page, the Delete column is present (see Figure 13).

Figure 12: The Delete Column is Not Rendered When Visited By Someone Other Than Tito (Such as Bruce) (Click to view full-size image)

Figure 13: The Delete Column is Rendered for Tito (Click to view full-size image)

Step 4: Applying Authorization Rules to Classes and Methods

In Step 3 we disallowed anonymous users from viewing a file's contents and prohibited all users but Tito from deleting files. This was accomplished by hiding the associated user interface elements for unauthorized visitors through declarative and programmatic techniques. For our simple example, properly hiding the user interface elements was straightforward, but what about more complex sites where there may be many different ways to perform the same functionality? In limiting that functionality to unauthorized users, what happens if we forget to hide or disable all of the applicable user interface elements?

An easy way to ensure that a particular piece of functionality cannot be accessed by an unauthorized user is to decorate that class or method with the `PrincipalPermission` attribute. When the .NET runtime uses a class or executes one of its methods, it checks to ensure that the current security context has permission to use the class or execute the method. The `PrincipalPermission` attribute provides a mechanism through which we can define these rules.

Let's demonstrate using the `PrincipalPermission` attribute on the GridView's `SelectedIndexChanged` and `RowDeleting` event handlers to prohibit execution by anonymous users and users other than Tito, respectively. All we need to do is add the appropriate attribute atop each function definition:

```
<PrincipalPermission(SecurityAction.Demand, Authenticated:=True)> _
Protected Sub FilesGrid_SelectedIndexChanged(ByVal sender As Object, ByVal e As System.EventArgs) Handles
FilesGrid.SelectedIndexChanged
 ...
End Sub

<PrincipalPermission(SecurityAction.Demand, Name:="Tito")> _
Protected Sub FilesGrid_RowDeleting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs) Handles FilesGrid.RowDeleting
 ...
End Sub
```

The attribute for the `SelectedIndexChanged` event handler dictates that only authenticated users can execute the event handler, where as the attribute on the `RowDeleting` event handler limits the execution to Tito.

> **NOTE**
>
> An attribute can be applied to a class, method, property, or event. When adding an attribute, it must be part of the class, method, property, or event declaration statement. Since Visual Basic uses line breaks as statement delimiters, attributes must either appear on the same line as the declaration or directly above it with a line continuation character (the underscore). In the code snippet above, the line continuation character is used to place the attribute on one line and the method declaration on another.

If, somehow, a user other than Tito attempts to execute the `RowDeleting` event handler or a non-authenticated user attempts to execute the `SelectedIndexChanged` event handler, the .NET runtime will raise a `SecurityException`.

Figure 14: If the Security Context is not Authorized to Execute the Method, a `SecurityException` is Thrown (Click to view full-size image)

> **NOTE**
>
> To allow multiple security contexts to access a class or method, decorate the class or method with a `PrincipalPermission` attribute for each security context. That is, to allow both Tito and Bruce to execute the `RowDeleting` event handler, add *two* `PrincipalPermission` attributes:

```
<PrincipalPermission(SecurityAction.Demand, Name:="Tito")> _

<PrincipalPermission(SecurityAction.Demand, Name:="Bruce")> _
```

In addition to ASP.NET pages, many applications also have an architecture that includes various layers, such as Business Logic and Data Access Layers. These layers are typically implemented as Class Libraries and offer classes and methods for performing business logic- and data-related functionality. The `PrincipalPermission` attribute is useful for applying authorization rules to these layers.

For more information on using the `PrincipalPermission` attribute to define authorization rules on classes and methods, refer to Scott Guthrie's blog entry Adding Authorization Rules to Business and Data Layers Using `PrincipalPermissionAttributes`.

Summary

In this tutorial we looked at how to apply user-based authorization rules. We started with a look at ASP.NET's URL authorization framework. On each request, the ASP.NET engine's `UrlAuthorizationModule` inspects the URL authorization rules defined in the application's configuration to determine whether the identity is authorized to access the requested resource. In short, URL authorization makes it easy to specify authorization rules for a specific page or for all pages in a particular directory.

The URL authorization framework applies authorization rules on a page-by-page basis. With URL authorization, either the requesting identity is authorized to access a particular resource or not. Many scenarios, however, call for more fine grain authorization rules. Rather than defining who is permitted to access a page, we may need to let everyone access a page, but to show different data or offer different functionality depending on the user visiting the page. Page-level authorization usually involves hiding specific user interface elements in order to prevent unauthorized users from accessing prohibited functionality. Additionally, it is possible to use attributes to restrict access to classes and execution of its methods for certain users.

Happy Programming!

> In this tutorial we will answer this question by building a very rudimentary guestbook application. In doing so, we will look at different options for modeling user information in a database, and then see how to associate this data with the user accounts created by the Membership framework.

Introduction

ASP.NET's Membership framework offers a flexible interface for managing users. The Membership API includes methods for validating credentials, retrieving information about the currently logged on user, creating a new user account, and deleting a user account, among others. Each user account in the Membership framework contains only the properties needed for validating credentials and performing essential user account-related tasks. This is evidenced by the methods and properties of the `MembershipUser` class, which models a user account in the Membership framework. This class has properties like `UserName`, `Email`, and `IsLockedOut`, and methods like `GetPassword` and `UnlockUser`.

Oftentimes, applications need to store additional user information not included in the Membership framework. For example, an online retailer might need to let each user store her shipping and billing addresses, payment information, delivery preferences, and contact phone number. Furthermore, each order in the system is associated with a particular user account.

The `MembershipUser` class does not include properties like `PhoneNumber` or `DeliveryPreferences` or `PastOrders`. So how do we track the user information needed by the application and have it integrate with the Membership framework? In this tutorial we will answer this question by building a very rudimentary guestbook application. In doing so, we will look at different options for modeling user information in a database, and then see how to associate this data with the user accounts created by the Membership framework. Let's get started!

Step 1: Creating the Guestbook Application's Data Model

There are a variety of techniques that can be employed to capture user information in a database and associate it with the user accounts created by the Membership framework. In order to illustrate these techniques, we will need to augment the tutorial web application so that it captures some sort of user-related data. (Currently, the application's data model contains only the application services tables needed by the `SqlMembershipProvider`.)

Let's create a very simple guestbook application where an authenticated user can leave a comment. In addition to storing guestbook comments, let's allow each user to store his home town, homepage, and signature. If provided, the user's home town, homepage, and signature will appear on each message he has left in the guestbook.

Adding the `GuestbookComments` Table

In order to capture the guestbook comments, we need to create a database table named `GuestbookComments` that has columns like `CommentId`, `Subject`, `Body`, and `CommentDate`. We also need to have each record in the `GuestbookComments` table reference the user who left the comment.

To add this table to our database, go to the Database Explorer in Visual Studio and drill down into the `SecurityTutorials` database. Right-click on the Tables folder and choose Add New Table. This brings up an interface that allows us to define the columns for the new table.

Figure 1: Add a New Table to the `SecurityTutorials` Database (Click to view full-size image)

Next, define the `GuestbookComments`'s columns. Start by adding a column named `CommentId` of type `uniqueidentifier`. This column will uniquely identify each comment in the guestbook, so disallow `NULL`s and mark it as the table's primary key. Rather than providing a value for the `CommentId` field on each `INSERT`, we can indicate that a new `uniqueidentifier` value should be automatically generated for this field on `INSERT` by setting the column's default value to `NEWID()`. After adding this first field, marking it as the primary key, and settings its default value, your screen should look similar to the screen shot shown in Figure 2.

Figure 2: Add a Primary Column Named `CommentId` (Click to view full-size image)

Next, add a column named `Subject` of type `nvarchar(50)` and a column named `Body` of type `nvarchar(MAX)`, disallowing `NULL`s in both columns. Following that, add a column named `CommentDate` of type `datetime`. Disallow `NULL`s and set the `CommentDate` column's default value to `getdate()`.

All that remains is to add a column that associates a user account with each guestbook comment. One option would be to add a column named `UserName` of type `nvarchar(256)`. This is a suitable choice when using a Membership provider other than the `SqlMembershipProvider`. But when using the `SqlMembershipProvider`, as we

are in this tutorial series, the `UserName` column in the `aspnet_Users` table is not guaranteed to be unique. The `aspnet_Users` table's primary key is `UserId` and is of type `uniqueidentifier`. Therefore, the `GuestbookComments` table needs a column named `UserId` of type `uniqueidentifier` (disallowing `NULL` values). Go ahead and add this column.

> **NOTE**
>
> As we discussed in the *Creating the Membership Schema in SQL Server* tutorial, the Membership framework is designed to enable multiple web applications with different user accounts to share the same user store. It does this by partitioning user accounts into different applications. And while each username is guaranteed to be unique within an application, the same username may be used in different applications using the same user store. There is a composite `UNIQUE` constraint in the `aspnet_Users` table on the `UserName` and `ApplicationId` fields, but not one on just the `UserName` field. Consequently, it is possible for the aspnet_Users table to have two (or more) records with the same `UserName` value. There is, however, a `UNIQUE` constraint on the `aspnet_Users` table's `UserId` field (since it is the primary key). A `UNIQUE` constraint is important because without it we cannot establish a foreign key constraint between the `GuestbookComments` and `aspnet_Users` tables.

After adding the `UserId` column, save the table by clicking on the Save icon in the Toolbar. Name the new table `GuestbookComments`.

We have one last issue to attend to with the `GuestbookComments` table: we need to create a foreign key constraint between the `GuestbookComments.UserId` column and the `aspnet_Users.UserId` column. To achieve this, click the Relationship icon in the Toolbar to launch the Foreign Key Relationships dialog box. (Alternatively, you can launch this dialog box by going to the Table Designer menu and choosing Relationships.)

Click the Add button in the lower left corner of the Foreign Key Relationships dialog box. This will add a new foreign key constraint, although we still need to define the tables that participate in the relationship.

Figure 3: Use the Foreign Key Relationships Dialog Box to Manage a Table's Foreign Key Constraints (Click to view full-size image)

Next, click the ellipses icon in the "Table and Columns Specifications" row on the right. This will launch the Tables and Columns dialog box, from which we can specify the primary key table and column and the foreign key column from the `GuestbookComments` table. In particular, select `aspnet_Users` and `UserId` as the primary key table and column, and `UserId` from the `GuestbookComments` table as the foreign key column (see Figure 4). After defining the primary and foreign key tables and columns, click OK to return to the Foreign Key Relationships dialog box.

Figure 4: Establish a Foreign Key Constraint Between the `aspnet_Users` and `GuesbookComments` Tables (Click to view full-size image)

At this point the foreign key constraint has been established. The presence of this constraint ensures relational integrity between the two tables by guaranteeing that there will never be a guestbook entry referring to a non-existent user account. By default, a foreign key constraint will disallow a parent record to be deleted if there are corresponding child records. That is, if a user makes one or more guestbook comments, and then we attempt to delete that user account, the delete will fail unless his guestbook comments are deleted first.

Foreign key constraints can be configured to automatically delete the associated child records when a parent record is deleted. In other words, we can setup this foreign key constraint so that a user's guestbook entries are automatically deleted when her user account is deleted. To accomplish this, expand the "INSERT And UPDATE Specification" section and set the "Delete Rule" property to Cascade.

Figure 5: Configure the Foreign Key Constraint to Cascade Deletes (Click to view full-size image)

To save the foreign key constraint, click the Close button to exit out of the Foreign Key Relationships. Then click the Save icon in the Toolbar to save the table and the this relationship.

Storing the User's Home Town, Homepage, and Signature

The `GuestbookComments` table illustrates how to store information that shares a one-to-many relationship with user accounts. Since each user account may have an arbitrary number of associated comments, this relationship is modeled by creating a table to hold the set of comments that includes a column that links back each comment to a particular user. When using the `SqlMembershipProvider`, this link is best established by creating a column

named `UserId` of type `uniqueidentifier` and a foreign key constraint between this column and `aspnet_Users.UserId`.

We now need to associate three columns with each user account to store the user's home town, homepage, and signature, which will appear in his guestbook comments. There are number of different ways to accomplish this:

- **Add new columns to the `aspnet_Users` or `aspnet_Membership` tables.** I would not recommend this approach because it modifies the schema used by the `SqlMembershipProvider`. This decision may come back to haunt you down the road. For example, what if a future version of ASP.NET uses a different `SqlMembershipProvider` schema. Microsoft may include a tool to migrate the ASP.NET 2.0 `SqlMembershipProvider` data to the new schema, but if you have modified the ASP.NET 2.0 `SqlMembershipProvider` schema, such a conversion may not be possible.

- **Use ASP.NET's Profile framework, defining a profile property for the home town, homepage, and signature.** ASP.NET includes a Profile framework that is designed to store additional user-specific data. Like the Membership framework, the Profile framework is built atop the provider model. The .NET Framework ships with a `SqlProfileProvider` that stores profile data in a SQL Server database. In fact, our database already has the table used by the `SqlProfileProvider` (`aspnet_Profile`), as it was added when we added the application services back in the *Creating the Membership Schema in SQL Server* tutorial. The main benefit of the Profile framework is that it allows for developers to define the profile properties in `Web.config` – no code needs to be written to serialize the profile data to and from the underlying data store. In short, it is incredibly easy to define a set of profile properties and to work with them in code. However, the Profile system leaves a lot to be desired when it comes to versioning, so if you have an application where you expect new user-specific properties to be added at a later time, or existing ones to be removed or modified, then the Profile framework may not be the best option. Moreover, the `SqlProfileProvider` stores the profile properties in a highly denormalized fashion, making it next to impossible to run queries directly against the profile data (such as, how many users have a home town of New York).
  For more information on the Profile framework, consult the "Further Readings" section at the end of this tutorial.

- **Add these three columns to a new table in the database and establish a one-to-one relationship between this table and `aspnet_Users`.** This approach involves a bit more work than with the Profile framework, but offers maximum flexibility in how the additional user properties are modeled in the database. This is the option we will use in this tutorial.

We will create a new table called `UserProfiles` to save the home town, homepage, and signature for each user. Right-click on the Tables folder in the Database Explorer window and choose to create a new table. Name the first column `UserId` and set its type to `uniqueidentifier`. Disallow `NULL` values and mark the column as a primary key. Next, add columns named: `HomeTown` of type `nvarchar(50)`; `HomepageUrl` of type `nvarchar(100)`; and Signature of type `nvarchar(500)`. Each of these three columns can accept a `NULL` value.

Figure 6: Create the `UserProfiles` Table (Click to view full-size image)

Save the table and name it `UserProfiles`. Lastly, establish a foreign key constraint between the `UserProfiles` table's `UserId` field and the `aspnet_Users.UserId` field. As we did with the foreign key constraint between the `GuestbookComments` and `aspnet_Users` tables, have this constraint cascade deletes. Since the `UserId` field in `UserProfiles` is the primary key, this ensures that there will be no more than one record in the `UserProfiles` table for each user account. This type of relationship is referred to as one-to-one.

Now that we have the data model created, we are ready to use it. In Steps 2 and 3 we will look at how the currently logged on user can view and edit their home town, homepage, and signature information. In Step 4 we will create the interface for authenticated users to submit new comments to the guestbook and view the existing ones.

Step 2: Displaying the User's Home Town, Homepage, and Signature

There are a variety of ways to allow the currently logged on user to view and edit his home town, homepage, and signature information. We could manually create the user interface with TextBox and Label controls or we could use one of the data Web controls, such as the DetailsView control. To perform the database `SELECT` and `UPDATE` statements we could write ADO.NET code in our page's code-behind class or, alternatively, employ a declarative approach with the SqlDataSource. Ideally our application would contain a tiered architecture, which we could either invoke programmatically from the page's code-behind class or declaratively via the ObjectDataSource control.

Since this tutorial series focuses on forms authentication, authorization, user accounts, and roles, there will not be a thorough discussion of these different data access options or why a tiered architecture is preferred over executing SQL statements directly from the ASP.NET page. I am going to walk through using a DetailsView and SqlDataSource – the quickest and easiest option – but the concepts discussed can certainly be applied to alternative Web controls and data access logic. For more information on working with data in ASP.NET, refer to my *Working with Data in ASP.NET 2.0* tutorial series.

Open the `AdditionalUserInfo.aspx` page in the `Membership` folder and add a DetailsView control to the page,

setting its ID property to `UserProfile` and clearing out its `Width` and `Height` properties. Expand the DetailsView's Smart Tag and choose to bind it to a new data source control. This will launch the DataSource Configuration Wizard (see Figure 7). The first step asks you to specify the data source type. Since we are going to connect directly to the `SecurityTutorials` database, choose the Database icon, specifying the `ID` as `UserProfileDataSource`.

Figure 7: Add a New SqlDataSource Control Named `UserProfileDataSource` (Click to view full-size image)

The next screen prompts for the database to use. We have already defined a connection string in `Web.config` for the `SecurityTutorials` database. This connection string name – `SecurityTutorialsConnectionString` – should be in the drop-down list. Select this option and click Next.

Figure 8: Choose `SecurityTutorialsConnectionString` from the Drop-Down List (Click to view full-size image)

The subsequent screen asks us to specify the table and columns to query. Choose the `UserProfiles` table from the drop-down list and check all of the columns.

Figure 9: Bring Back All of the Columns from the `UserProfiles` Table (Click to view full-size image)

The current query in Figure 9 returns *all* of the records in `UserProfiles`, but we are only interested in the currently logged on user's record. To add a `WHERE` clause, click the `WHERE` button to bring up the Add `WHERE` Clause dialog box (see Figure 10). Here you can select the column to filter on, the operator, and the source of the filter parameter. Select `UserId` as the column and "=" as the Operator.

Unfortunately there is no built-in parameter source to return the currently logged on user's `UserId` value. We will need to grab this value programmatically. Therefore, set the Source drop-down list to "None," click the Add button to add the parameter, and then click OK.

Figure 10: Add a Filter Parameter on the `UserId` Column (Click to view full-size image)

After clicking OK you will be returned to the screen shown in Figure 9. This time, however, the SQL query at the bottom of the screen should include a `WHERE` clause. Click Next to move on to the "Test Query" screen. Here you can run the query and see the results. Click Finish to complete the wizard.

Upon completing the DataSource Configuration Wizard, Visual Studio creates the SqlDataSource control based on the settings specified in the wizard. Moreover, it manually adds BoundFields to the DetailsView for each

column returned by the SqlDataSource's `SelectCommand`. There's no need to show the `UserId` field in the DetailsView, since the user does not need to know this value. You can remove this field directly from the DetailsView control's declarative markup or by clicking the "Edit Fields" link from its Smart Tag.

At this point your page's declarative markup should look similar to the following:

```
<asp:DetailsView ID="UserProfile" runat="server"
          AutoGenerateRows="False" DataKeyNames="UserId"

          DataSourceID="UserProfileDataSource">
     <Fields>
          <asp:BoundField DataField="HomeTown" HeaderText="HomeTown"
               SortExpression="HomeTown" />
          <asp:BoundField DataField="HomepageUrl" HeaderText="HomepageUrl"

               SortExpression="HomepageUrl" />
          <asp:BoundField DataField="Signature" HeaderText="Signature"
               SortExpression="Signature" />
     </Fields>

</asp:DetailsView>
<asp:SqlDataSource ID="UserProfileDataSource" runat="server"
          ConnectionString="<%$ ConnectionStrings:SecurityTutorialsConnectionString %>"
          SelectCommand="SELECT [UserId], [HomeTown], [HomepageUrl], [Signature] FROM
          [UserProfiles] WHERE ([UserId] = @UserId)">
     <SelectParameters>

          <asp:Parameter Name="UserId" Type="Object" />
     </SelectParameters>
</asp:SqlDataSource>
```

We need to programmatically set the SqlDataSource control's `UserId` parameter to the currently logged in user's `UserId` before the data is selected. This can be accomplished by creating an event handler for the SqlDataSource's `Selecting` event and adding the following code there:

```
Protected Sub UserProfileDataSource_Selecting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.SqlDataSourceSelectingEventArgs) Handles UserProfileDataSource.Selecting
     ' Get a reference to the currently logged on user
     Dim currentUser As MembershipUser = Membership.GetUser()

     ' Determine the currently logged on user's UserId value
     Dim currentUserId As Guid = CType(currentUser.ProviderUserKey, Guid)

     ' Assign the currently logged on user's UserId to the @UserId parameter
     e.Command.Parameters("@UserId").Value = currentUserId
End Sub
```

The above code starts by obtaining a reference to the currently logged on user by calling the `Membership` class's `GetUser` method. This returns a `MembershipUser` object, whose `ProviderUserKey` property contains the `UserId`. The `UserId` value is then assigned to the SqlDataSource's `@UserId` parameter.

> **NOTE**
>
> The `Membership.GetUser()` method returns information about the currently logged on user. If an anonymous user is visiting the page, it will return a value of `Nothing`. In such a case, this will lead to a `NullReferenceException` on the following line of code when attempting to read the `ProviderUserKey` property. Of course, we don't have to worry about `Membership.GetUser()` returning Nothing in the `AdditionalUserInfo.aspx` page because we configured URL authorization in a previous tutorial so that only authenticated users could access the ASP.NET resources in this folder. If you need to access information about the currently logged on user in a page where anonymous access is permitted, make sure to check that the `MembershipUser` object returned from the `GetUser()` method is not Nothing before referencing its properties.

If you visit the `AdditionalUserInfo.aspx` page through a browser you will see a blank page because we have yet to add any rows to the `UserProfiles` table. In Step 6 we will look at how to customize the CreateUserWizard control to automatically add a new row to the `UserProfiles` table when a new user account is created. For now, however, we will need to manually create a record in the table.

Navigate to the Database Explorer in Visual Studio and expand the Tables folder. Right-click on the `aspnet_Users` table and choose "Show Table Data" to see the records in the table; do the same thing for the `UserProfiles` table. Figure 11 shows these results when tiled vertically. In my database there are currently `aspnet_Users` records for Bruce, Fred, and Tito, but no records in the `UserProfiles` table.

Figure 11: The Contents of the `aspnet_Users` and `UserProfiles` Tables are Displayed (Click to view full-size image)

Add a new record to the `UserProfiles` table by manually typing in values for the `HomeTown`, `HomepageUrl`, and `Signature` fields. The easiest way to get a valid `UserId` value in the new `UserProfiles` record is to select the `UserId` field from a particular user account in the `aspnet_Users` table and copy and paste it into the `UserId` field in `UserProfiles`. Figure 12 shows the `UserProfiles` table after a new record has been added for Bruce.

Figure 12: A Record was Added to `UserProfiles` for Bruce (Click to view full-size image)

Return to the `AdditionalUserInfo.aspx page`, logged in as Bruce. As Figure 13 shows, Bruce's settings are displayed.

Figure 13: The Currently Visiting User is Shown His Settings (Click to view full-size image)

> **NOTE**
>
> Go ahead and manually add records in the `UserProfiles` table for each Membership user. In Step 6 we will look at how to customize the CreateUserWizard control to automatically add a new row to the `UserProfiles` table when a new user account is created.

Step 3: Allowing the User to Edit His Home Town, Homepage, and Signature

At this point the currently logged in user can view their home town, homepage, and signature setting, but they cannot yet modify them. Let's update the DetailsView control so that the data can be edited.

The first thing we need to do is add an `UpdateCommand` for the SqlDataSource, specifying the `UPDATE` statement to

execute and its corresponding parameters. Select the SqlDataSource and, from the Properties window, click on the ellipses next to the UpdateQuery property to bring up the Command and Parameter Editor dialog box. Enter the following `UPDATE` statement into the textbox:

```
UPDATE UserProfiles SET
     HomeTown = @HomeTown,
     HomepageUrl = @HomepageUrl,
     Signature = @Signature
WHERE UserId = @UserId
```

Next, click the "Refresh Parameters" button, which will create a parameter in the SqlDataSource control's `UpdateParameters` collection for each of the parameters in the `UPDATE` statement. Leave the source for all of the parameters set to None and click the OK button to complete the dialog box.

Figure 14: Specify the SqlDataSource's `UpdateCommand` and `UpdateParameters` (Click to view full-size image)

Due to the additions we made to the SqlDataSource control, the DetailsView control can now support editing. From the DetailsView's Smart Tag, check the "Enable Editing" checkbox. This adds a CommandField to the control's `Fields` collection with its `ShowEditButton` property set to True. This renders an Edit button when the DetailsView is displayed in read-only mode and Update and Cancel buttons when displayed in edit mode. Rather than requiring the user to click Edit, though, we can have the DetailsView render in an "always editable" state by setting the DetailsView control's `DefaultMode` property to `Edit`.

With these changes, your DetailsView control's declarative markup should look similar to the following:

```
<asp:DetailsView ID="UserProfile" runat="server"

          AutoGenerateRows="False" DataKeyNames="UserId"
          DataSourceID="UserProfileDataSource" DefaultMode="Edit">
     <Fields>
          <asp:BoundField DataField="HomeTown" HeaderText="HomeTown"

               SortExpression="HomeTown" />
          <asp:BoundField DataField="HomepageUrl" HeaderText="HomepageUrl"
               SortExpression="HomepageUrl" />
          <asp:BoundField DataField="Signature" HeaderText="Signature"

               SortExpression="Signature" />
          <asp:CommandField ShowEditButton="True" />
     </Fields>
</asp:DetailsView>
```

Note the addition of the CommandField and the `DefaultMode` property.

Go ahead and test this page through a browser. When visiting with a user that has a corresponding record in `UserProfiles`, the user's settings are displayed in an editable interface.

Figure 15: The DetailsView Renders an Editable Interface (Click to view full-size image)

Try changing the values and clicking the Update button. It appears as if nothing happens. There is a postback and the values are saved to the database, but there's no visual feedback that the save occurred.

To remedy this, return to Visual Studio and add a Label control above the DetailsView. Set its `ID` to `SettingsUpdatedMessage`, its `Text` property to "Your settings have been updated," and its `Visible` and `EnableViewState` properties to `False`.

```
<asp:Label ID="SettingsUpdatedMessage" runat="server"
     Text="Your settings have been updated."
     EnableViewState="false"
     Visible="false">
</asp:Label>
```

We need to display the `SettingsUpdatedMessage` Label whenever the DetailsView is updated. To accomplish this, create an event handler for the DetailsView's `ItemUpdated` event and add the following code:

```
Protected Sub UserProfile_ItemUpdated(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.DetailsViewUpdatedEventArgs) Handles UserProfile.ItemUpdated
     SettingsUpdatedMessage.Visible = True
End Sub
```

Return to the `AdditionalUserInfo.aspx` page through a browser and update the data. This time, a helpful status message is displayed.

Figure 16: A Short Message is Displayed When the Settings are Updated (Click to view full-size image)

> **NOTE**
>
> The DetailsView control's editing interface leaves a lot to be desired. It uses standard-sized textboxes, but the Signature field should probably be a multi-line textbox. A RegularExpressionValidator should be used to ensure that the homepage URL, if entered, starts with "http://" or "https://". Moreover, since the DetailsView control has its `DefaultMode` property set to `Edit`, the Cancel button does not do anything. It should either be removed or, when clicked, redirect the user to some other page (such as `~/Default.aspx`). I leave these enhancements as an exercise for the reader.

Adding a Link to the `AdditionalUserInfo.aspx` Page in the Master Page

Currently, the website does not provide any links to the `AdditionalUserInfo.aspx` page. The only way to reach it is to enter the page's URL directly into the browser's Address bar. Let's add a link to this page in the `Site.master` master page.

Recall that the master page contains a LoginView Web control in its `LoginContent` ContentPlaceHolder that displays different markup for authenticated and anonymous visitors. Update the LoginView control's `LoggedInTemplate` to include a link to the `AdditionalUserInfo.aspx` page. After making these changes the LoginView control's declarative markup should look similar to the following:

```
<asp:LoginView ID="LoginView1" runat="server">
     <LoggedInTemplate>
          Welcome back,
          <asp:LoginName ID="LoginName1" runat="server" />.

          <br />
          <asp:HyperLink ID="lnkUpdateSettings" runat="server"
               NavigateUrl="~/Membership/AdditionalUserInfo.aspx">
               Update Your Settings</asp:HyperLink>
     </LoggedInTemplate>
     <AnonymousTemplate>

          Hello, stranger.
     </AnonymousTemplate>
</asp:LoginView>
```

Note the addition of the `lnkUpdateSettings` HyperLink control to the `LoggedInTemplate`. With this link in place, authenticated users can quickly jump to the page to view and modify their home town, homepage, and signature settings.

Step 4: Adding New Guestbook Comments

The `Guestbook.aspx` page is where authenticated users can view the guestbook and leave a comment. Let's start with creating the interface to add new guestbook comments.

Open the `Guestbook.aspx` page in Visual Studio and construct a user interface consisting of two TextBox controls, one for the new comment's subject and one for its body. Set the first TextBox control's `ID` property to `Subject` and its `Columns` property to 40; set second's `ID` to `Body`, its `TextMode` to `MultiLine`, and its `Width` and `Rows` properties to "95%" and 8, respectively. To complete the user interface, add a Button Web control named `PostCommentButton` and set its `Text` property to "Post Your Comment".

Since each guestbook comment requires a subject and body, add a RequiredFieldValidator for each of the TextBoxes. Set the `ValidationGroup` property of these controls to "EnterComment"; likewise, set the `PostCommentButton` control's `ValidationGroup` property to "EnterComment". For more information on ASP.NET's validation controls, check out Form Validation in ASP.NET, Dissecting the Validation Controls in ASP.NET 2.0, and the Validation Server Controls Tutorial on W3Schools.

After crafting the user interface your page's declarative markup should look something like the following:

```
<h3>Leave a Comment</h3>
<p>
     <b>Subject:</b>
     <asp:RequiredFieldValidator ID="SubjectReqValidator" runat="server"

          ErrorMessage="You must provide a value for Subject"
          ControlToValidate="Subject" ValidationGroup="EnterComment">
     </asp:RequiredFieldValidator><br />
     <asp:TextBox ID="Subject" Columns="40" runat="server"></asp:TextBox>

</p>
<p>
     <b>Body:</b>
     <asp:RequiredFieldValidator ID="BodyReqValidator" runat="server"
          ControlToValidate="Body"

          ErrorMessage="You must provide a value for Body" ValidationGroup="EnterComment">
     </asp:RequiredFieldValidator><br />
     <asp:TextBox ID="Body" TextMode="MultiLine" Width="95%"

          Rows="8" runat="server"></asp:TextBox>
</p>
<p>
     <asp:Button ID="PostCommentButton" runat="server"

          Text="Post Your Comment"
          ValidationGroup="EnterComment" />
</p>
```

With the user interface complete, our next task is to insert a new record into the `GuestbookComments` table when the `PostCommentButton` is clicked. This can be accomplished in a number of ways: we can write ADO.NET code in the Button's `Click` event handler; we can add a SqlDataSource control to the page, configure its `InsertCommand`, and then call its `Insert` method from the `Click` event handler; or we could build a middle tier that was responsible for inserting new guestbook comments, and invoke this functionality from the `Click` event handler. Since we looked at using a SqlDataSource in Step 3, let's use ADO.NET code here.

> **NOTE**
>
> The ADO.NET classes used to programmatically access data from a Microsoft SQL Server database are located in the `System.Data.SqlClient` namespace. You may need to import this namespace into your page's code-behind class (i.e., `Imports System.Data.SqlClient`).

Create an event handler for the `PostCommentButton`'s `Click` event and add the following code:

```
Protected Sub PostCommentButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
PostCommentButton.Click
     If Not Page.IsValid Then Exit Sub

     ' Determine the currently logged on user's UserId
     Dim currentUser As MembershipUser = Membership.GetUser()
     Dim currentUserId As Guid = CType(currentUser.ProviderUserKey, Guid)

     ' Insert a new record into GuestbookComments
     Dim connectionString As String =
          ConfigurationManager.ConnectionStrings("SecurityTutorialsConnectionString").ConnectionString
     Dim insertSql As String = "INSERT INTO GuestbookComments(Subject, Body, UserId)
          VALUES(@Subject, @Body, @UserId)"

     Using myConnection As New SqlConnection(connectionString)

          myConnection.Open()
          Dim myCommand As New SqlCommand(insertSql, myConnection)
          myCommand.Parameters.AddWithValue("@Subject", Subject.Text.Trim())
          myCommand.Parameters.AddWithValue("@Body", Body.Text.Trim())
          myCommand.Parameters.AddWithValue("@UserId", currentUserId)
          myCommand.ExecuteNonQuery()
          myConnection.Close()
     End Using

     ' "Reset" the Subject and Body TextBoxes

     Subject.Text = String.Empty
     Body.Text = String.Empty
End Sub
```

The `Click` event handler starts by checking that the user-supplied data is valid. If it is not, the event handler exits before inserting a record. Assuming the supplied data is valid, the currently logged on user's `UserId` value is retrieved and stored in the `currentUserId` local variable. This value is needed because we must supply a `UserId` value when inserting a record into `GuestbookComments`.

Following that, the connection string for the `SecurityTutorials` database is retrieved from `Web.config` and the `INSERT` SQL statement is specified. A `SqlConnection` object is then created and opened. Next, a `SqlCommand` object is constructed and the values for the parameters used in the `INSERT` query are assigned. The `INSERT` statement is then executed and the connection closed. At the end of the event handler, the `Subject` and `Body` TextBoxes' `Text` properties are cleared out so that the user's values are not persisted across the postback.

Go ahead and test out this page in a browser. Since this page is in the `Membership` folder it is not accessible to anonymous visitors. Therefore, you will need to first log on (if you have not already). Enter a value into the `Subject` and `Body` TextBoxes and click the `PostCommentButton` button. This will cause a new record to be added to `GuestbookComments`. On postback, the subject and body you provided are wiped from the TextBoxes.

After clicking the `PostCommentButton` button there is no visual feedback that the comment was added to the guestbook. We still need to update this page to display the existing guestbook comments, which we will do in Step 5. Once we accomplish that, the just-added comment will appear in the list of comments, providing adequate visual feedback. For now, confirm that your guestbook comment was saved by examining the contents of the `GuestbookComments` table.

Figure 17 shows the contents of the `GuestbookComments` table after two comments have been left.

Figure 17: You Can See the Guestbook Comments in the `GuestbookComments` Table (Click to view full-size image)

> **NOTE**
>
> If a user attempts to insert a guestbook comment that contains potentially dangerous markup – such as HTML – ASP.NET will throw an `HttpRequestValidationException`. To learn more about this exception, why it's thrown, and how to permit users to submit potentially dangerous values, consult the Request Validation Whitepaper.

Step 5: Listing the Existing Guestbook Comments

In addition to leaving comments, a user visiting the `Guestbook.aspx` page should also be able to view the guestbook's existing comments. To accomplish this, add a ListView control named `CommentList` to the bottom of the page.

> **NOTE**
>
> The ListView control is new to ASP.NET version 3.5. It is designed to display a list of items in a very customizable and flexible layout, yet still offer built-in editing, inserting, deleting, paging, and sorting functionality like the GridView. If you are using ASP.NET 2.0, you will need to use the DataList or Repeater control instead. For more information on using the ListView, see Scott Guthrie's blog entry, The asp:ListView Control, and my article, Displaying Data with the ListView Control.

Open the ListView's Smart Tag and, from the Choose Data Source drop-down list, bind the control to a new data source. As we saw in Step 2, this will launch the Data Source Configuration Wizard. Select the Database icon, name the resulting SqlDataSource `CommentsDataSource`, and click OK. Next, select the `SecurityTutorialsConnectionString` connection string from the drop-down list and click Next.

At this point in Step 2 we specified the data to query by picking the `UserProfiles` table from the drop-down list and selecting the columns to return (refer back to Figure 9). This time, however, we want to craft a SQL statement that pulls back not only the records from `GuestbookComments`, but also the commenter's home town, homepage, signature, and username. Therefore, select the "Specify a custom SQL statement or stored procedure" radio button and click Next.

This will bring up the "Define Custom Statements or Stored Procedures" screen. Click the Query Builder button to graphically build the query. The Query Builder starts by prompting us to specify the tables we want to query from. Select the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` tables and click OK. This will add all three tables to the design surface. Since there are foreign key constraints amongst the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` tables, the Query Builder automatically `JOIN` s these tables.

All that remains is to specify the columns to return. From the `GuestbookComments` table select the `Subject`, `Body`, and `CommentDate` columns; return the `HomeTown`, `HomepageUrl`, and `Signature` columns from the `UserProfiles` table; and return `UserName` from `aspnet_Users`. Also, add "`ORDER BY CommentDate DESC`" to the end of the `SELECT` query so that the most recent posts are returned first. After making these selections, your Query Builder interface should look similar to the screen shot in Figure 18.

Figure 18: The Constructed Query `JOIN` s the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` Tables (Click to view full-size image)

Click OK to close the Query Builder window and return to the "Define Custom Statements or Stored Procedures" screen. Click Next to advance to the "Test Query" screen, where you may view the query results by clicking the Test Query button. When you're ready, click Finish to complete the Configure Data Source wizard.

When we completed the Configure Data Source wizard in Step 2, the associated DetailsView control's `Fields` collection was updated to include a BoundField for each column returned by the `SelectCommand`. The ListView, however, remains unchanged; we still need to define its layout. The ListView's layout can be constructed manually through its declarative markup or from the "Configure ListView" option in its Smart Tag. I usually prefer defining the markup by hand, but use whatever method is most natural to you.

I ended up using the following `LayoutTemplate`, `ItemTemplate`, and `ItemSeparatorTemplate` for my ListView control:

```
<asp:ListView ID="CommentList" runat="server" DataSourceID="CommentsDataSource">

     <LayoutTemplate>
          <span ID="itemPlaceholder" runat="server" />
          <p>
               <asp:DataPager ID="DataPager1" runat="server">

                    <Fields>
                         <asp:NextPreviousPagerField ButtonType="Button"
                              ShowFirstPageButton="True"
                              ShowLastPageButton="True" />
                    </Fields>
               </asp:DataPager>

          </p>
     </LayoutTemplate>
     <ItemTemplate>
          <h4>
               <asp:Label ID="SubjectLabel" runat="server"
                    Text='<%# Eval("Subject") %>' />

          </h4>
          <asp:Label ID="BodyLabel" runat="server"
               Text='<%# Eval("Body").ToString().Replace(Environment.NewLine, "<br />") %>' />
          <p>

          ---<br />
          <asp:Label ID="SignatureLabel" Font-Italic="true" runat="server"
               Text='<%# Eval("Signature") %>' />

          <br />
          <br />
          My Home Town:
          <asp:Label ID="HomeTownLabel" runat="server"
               Text='<%# Eval("HomeTown") %>' />

          <br />
          My Homepage:
          <asp:HyperLink ID="HomepageUrlLink" runat="server"
               NavigateUrl='<%# Eval("HomepageUrl") %>'
               Text='<%# Eval("HomepageUrl") %>' />

          </p>
          <p align="center">
          Posted by
          <asp:Label ID="UserNameLabel" runat="server"
               Text='<%# Eval("UserName") %>' />

          on
          <asp:Label ID="CommentDateLabel" runat="server"
               Text='<%# Eval("CommentDate") %>' />
          </p>
     </ItemTemplate>

     <ItemSeparatorTemplate>
          <hr />
     </ItemSeparatorTemplate>
</asp:ListView>
```

The `LayoutTemplate` defines the markup emitted by the control, while the `ItemTemplate` renders each item returned by the SqlDataSource. The `ItemTemplate`'s resulting markup is placed in the `LayoutTemplate`'s `itemPlaceholder` control. In addition to the `itemPlaceholder`, the `LayoutTemplate` includes a DataPager control, which limits the ListView to showing just 10 guestbook comments per page (the default) and renders a paging interface.

My `ItemTemplate` displays each guestbook comment's subject in an `<h4>` element with the body situated below the subject. Note that syntax used for displaying the body takes the data returned by the `Eval("Body")` databinding statement, converts it to a string, and replaces line breaks with the `<br />` element. This conversion is needed in order to show the line breaks entered when submitting the comment since whitespace is ignored by HTML. The user's signature is displayed beneath the body in italics, followed by the user's home town, a link to his homepage, the date and time the comment was made, and the username of the person who left the comment.

Take a moment to view the page through a browser. You should see the comments that you added to the guestbook in Step 5 displayed here.

Figure 19: `Guestbook.aspx` Now Displays the Guestbook's Comments (Click to view full-size image)

Try adding a new comment to the guestbook. Upon clicking the `PostCommentButton` button the page posts back and the comment is added to the database, but the ListView control is not updated to show the new comment. This can be fixed by either:

- Updating the `PostCommentButton` button's `Click` event handler so that it invokes the ListView control's `DataBind()` method after inserting the new comment into the database, or
- Setting the ListView control's `EnableViewState` property to `False`. This approach works because by disabling the control's view state, it must rebind to the underlying data on every postback.

The tutorial website downloadable from this tutorial illustrates both techniques. The ListView control's `EnableViewState` property to `False` and the code needed to programmatically rebind the data to the ListView is present in the `Click` event handler, but is commented out.

> **NOTE**
>
> Currently the `AdditionalUserInfo.aspx` page allows the user to view and edit their home town, homepage, and signature settings. It might be nice to update `AdditionalUserInfo.aspx` to display the logged in user's guestbook comments. That is, in addition to examining and modifying her information, a user can visit the `AdditionalUserInfo.aspx` page to see what guestbook comments she's made in the past. I leave this as an exercise for the interested reader.

Step 6: Customizing the CreateUserWizard Control to Include an Interface for the Home Town, Homepage, and Signature

The `SELECT` query used by the `Guestbook.aspx` page uses an `INNER JOIN` to combine the related records amongst the `GuestbookComments`, `UserProfiles`, and `aspnet_Users` tables. If a user that has no record in `UserProfiles` makes a guestbook comment, the comment won't be displayed in the ListView because the `INNER JOIN` only returns `GuestbookComments` records when there are matching records in `UserProfiles` and `aspnet_Users`. And as we saw in Step 3, if a user does not have a record in `UserProfiles` she cannot view or edit her settings in the `AdditionalUserInfo.aspx` page.

Needless to say, due to our design decisions it is important that every user account in the Membership system have a matching record in the `UserProfiles` table. What we want is for a corresponding record to be added to `UserProfiles` whenever a new Membership user account is created through the CreateUserWizard.

As discussed in the *Creating User Accounts* tutorial, after the new Membership user account is created the CreateUserWizard control raises its `CreatedUser` event. We can create an event handler for this event, get the UserId for the just-created user, and then insert a record into the `UserProfiles` table with default values for the `HomeTown`, `HomepageUrl`, and `Signature` columns. What's more, it is possible to prompt the user for these values by customizing the CreateUserWizard control's interface to include additional TextBoxes.

Let's first look at how to add a new row to the `UserProfiles` table in the `CreatedUser` event handler with default values. Following that, we will see how to customize the CreateUserWizard control's user interface to include additional form fields to collect the new user's home town, homepage, and signature.

Adding a Default Row to `UserProfiles`

In the *Creating User Accounts* tutorial we added a CreateUserWizard control to the `CreatingUserAccounts.aspx` page in the `Membership` folder. In order to have the CreateUserWizard control add a record to `UserProfiles` table upon user account creation, we need to update the CreateUserWizard control's functionality. Rather than making these changes to the `CreatingUserAccounts.aspx` page, let's instead add a new CreateUserWizard control to `EnhancedCreateUserWizard.aspx` page and make the modifications for this tutorial there.

Open the `EnhancedCreateUserWizard.aspx` page in Visual Studio and drag a CreateUserWizard control from the Toolbox onto the page. Set the CreateUserWizard control's `ID` property to `NewUserWizard`. As we discussed in the *Creating User Accounts* tutorial, the CreateUserWizard's default user interface prompts the visitor for the necessary information. Once this information has been supplied, the control internally creates a new user account in the Membership framework, all without us having to write a single line of code.

The CreateUserWizard control raises a number of events during its workflow. After a visitor supplies the request information and submits the form, the CreateUserWizard control initially fires its `CreatingUser` event. If there is a problem during the create process, the `CreateUserError` event is fired; however, if the user is successfully created, then the `CreatedUser` event is raised. In the *Creating User Accounts* tutorial we created an event handler for the `CreatingUser` event to ensure that the supplied username did not contain any leading or trailing spaces, and that the username did not appear anywhere in the password.

In order to add a row in the `UserProfiles` table for the just-created user, we need to create an event handler for the `CreatedUser` event. By the time the `CreatedUser` event has fired, the user account has already been created in the Membership framework, enabling us to retrieve the account's UserId value.

Create an event handler for the `NewUserWizard`'s `CreatedUser` event and add the following code:

```
Protected Sub NewUserWizard_CreatedUser(ByVal sender As Object, ByVal e As System.EventArgs) Handles
NewUserWizard.CreatedUser
     ' Get the UserId of the just-added user
     Dim newUser As MembershipUser = Membership.GetUser(NewUserWizard.UserName)
     Dim newUserId As Guid = CType(newUser.ProviderUserKey, Guid)

     ' Insert a new record into UserProfiles
     Dim connectionString As String =

          ConfigurationManager.ConnectionStrings("SecurityTutorialsConnectionString").ConnectionString
     Dim insertSql As String = "INSERT INTO UserProfiles(UserId, HomeTown, HomepageUrl,
          Signature) VALUES(@UserId, @HomeTown, @HomepageUrl, @Signature)"

     Using myConnection As New SqlConnection(connectionString)
          myConnection.Open()
          Dim myCommand As New SqlCommand(insertSql, myConnection)
          myCommand.Parameters.AddWithValue("@UserId", newUserId)
          myCommand.Parameters.AddWithValue("@HomeTown", DBNull.Value)

          myCommand.Parameters.AddWithValue("@HomepageUrl", DBNull.Value)
          myCommand.Parameters.AddWithValue("@Signature", DBNull.Value)
          myCommand.ExecuteNonQuery()
          myConnection.Close()
     End Using
End Sub
```

The above code beings by retrieving the UserId of the just-added user account. This is accomplished by using the `Membership.GetUser(username)` method to return information about a particular user, and then using the `ProviderUserKey` property to retrieve their UserId. The username entered by the user in the CreateUserWizard control is available via its `UserName` property.

Next, the connection string is retrieved from `Web.config` and the `INSERT` statement is specified. The necessary ADO.NET objects are instantiated and the command executed. The code assigns a `DBNull` instance to the `@HomeTown`, `@HomepageUrl`, and `@Signature` parameters, which has the effect of inserting database `NULL` values for the `HomeTown`, `HomepageUrl`, and `Signature` fields.

Visit the `EnhancedCreateUserWizard.aspx` page through a browser and create a new user account. After doing so, return to Visual Studio and examine the contents of the `aspnet_Users` and `UserProfiles` tables (like we did back in Figure 12). You should see the new user account in `aspnet_Users` and a corresponding `UserProfiles` row (with `NULL` values for `HomeTown`, `HomepageUrl`, and `Signature`).

Figure 20: A New User Account and `UserProfiles` Record Have Been Added (Click to view full-size image)

After the visitor has supplied his new account information and clicked the "Create User" button, the user account is created and a row added to the `UserProfiles` table. The CreateUserWizard then displays its `CompleteWizardStep`, which displays a success message and a Continue button. Clicking the Continue button causes a postback, but no action is taken, leaving the user stuck on the `EnhancedCreateUserWizard.aspx` page.

We can specify a URL to send the user to when the Continue button is clicked via the CreateUserWizard control's `ContinueDestinationPageUrl` property. Set the `ContinueDestinationPageUrl` property to "~/Membership/AdditionalUserInfo.aspx". This takes the new user to `AdditionalUserInfo.aspx`, where they can view and update their settings.

Customizing the CreateUserWizard's Interface to Prompt for the New User's Home Town, Homepage, and Signature

The CreateUserWizard control's default interface is sufficient for simple account creation scenarios where only core user account information like username, password, and email need be collected. But what if we wanted to prompt the visitor to enter her home town, homepage, and signature while creating her account? It is possible to customize the CreateUserWizard control's interface to collect additional information at signup, and this information may be used in the `CreatedUser` event handler to insert additional records into the underlying database.

The CreateUserWizard control extends the ASP.NET Wizard control, which is a control that allows a page developer to define a series of ordered `WizardSteps`. The Wizard control renders the active step and provides a navigation interface that allows the visitor to move through these steps. The Wizard control is ideal for breaking down a long task into several short steps. For more information on the Wizard control, see Creating a Step-by-Step User Interface with the ASP.NET 2.0 Wizard Control.

The CreateUserWizard control's default markup defines two `WizardSteps`: `CreateUserWizardStep` and `CompleteWizardStep`.

```
<asp:CreateUserWizard ID="NewUserWizard" runat="server"
          ContinueDestinationPageUrl="~/Membership/AdditionalUserInfo.aspx">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">

          </asp:CreateUserWizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

The first `WizardStep`, `CreateUserWizardStep`, renders the interface that prompts for the username, password, email, and so on. After the visitor supplies this information and clicks "Create User", she is shown the `CompleteWizardStep`, which shows the success message and a Continue button.

To customize the CreateUserWizard control's interface to include additional form fields, we can:

- **Create one or more new `WizardStep`s to contain the additional user interface elements**. To add a new `WizardStep` to the CreateUserWizard, click the "Add/Remove `WizardStep` s" link from its Smart Tag to launch the `WizardStep` Collection Editor. From there you can add, remove, or reorder the steps in the wizard. This is the approach we will use for this tutorial.
- **Convert the `CreateUserWizardStep` into an editable `WizardStep`**. This replaces the `CreateUserWizardStep` with an equivalent `WizardStep` whose markup defines a user interface that matches the `CreateUserWizardStep`'s. By converting the `CreateUserWizardStep` into a `WizardStep` we can reposition the controls or add additional user interface elements to this step. To convert the `CreateUserWizardStep` or `CompleteWizardStep` into an editable `WizardStep`, click the "Customize Create User Step" or "Customize Complete Step" link from the control's Smart Tag.

- Use some combination of the above two options.

One important thing to keep in mind is that the CreateUserWizard control executes its user account creation process when the "Create User" button is clicked from within its `CreateUserWizardStep`. It doesn't matter if there are additional `WizardStep` s after the `CreateUserWizardStep` or not.

When adding a custom `WizardStep` to the CreateUserWizard control to collect additional user input, the custom `WizardStep` can be placed before or after the `CreateUserWizardStep`. If it comes before the `CreateUserWizardStep` then the additional user input collected from the custom `WizardStep` is available for the `CreatedUser` event handler. However, if the custom `WizardStep` comes after `CreateUserWizardStep` then by the time the custom `WizardStep` is displayed the new user account has already been created and the `CreatedUser` event has already fired.

Figure 21 shows the workflow when the added `WizardStep` precedes the `CreateUserWizardStep`. Since the additional user information has been collected by the time the `CreatedUser` event fires, all we have to do is update the `CreatedUser` event handler to retrieve these inputs and use those for the `INSERT` statement's parameter values (rather than `DBNull.Value`).

Figure 21: The CreateUserWizard Workflow When an Additional `WizardStep` Precedes the `CreateUserWizardStep` (Click to view full-size image)

If the custom `WizardStep` is placed *after* the `CreateUserWizardStep`, however, the create user account process occurs before the user has had a chance to enter her home town, homepage, or signature. In such a case, this additional information needs to be inserted into the database after the user account has been created, as Figure 22 illustrates.

Figure 22: The CreateUserWizard Workflow When an Additional `WizardStep` Comes After the `CreateUserWizardStep` (Click to view full-size image)

The workflow shown in Figure 22 waits to insert a record into the `UserProfiles` table until after Step 2 completes. If the visitor closes her browser after step 1, however, we will have reached a state where a user account was created, but no record was added to `UserProfiles`. One workaround is to have a record with `NULL` or default values inserted into `UserProfiles` in the `CreatedUser` event handler (which fires after step 1), and then update this record after step 2 completes. This ensures that a `UserProfiles` record will be added for the user account even if the user quits the registration process midway through.

For this tutorial let's create a new `WizardStep` that occurs after the `CreateUserWizardStep` but before the `CompleteWizardStep`. Let's first get the WizardStep in place and configured and then we'll look at the code.

From the CreateUserWizard control's Smart Tag, select the "Add/Remove `WizardStep` s", which brings up the `WizardStep` Collection Editor dialog. Add a new `WizardStep`, setting its `ID` to `UserSettings`, its `Title` to "Your Settings" and its `StepType` to `Step`. Then position it so that it comes after the `CreateUserWizardStep` ("Sign Up for Your New Account") and before the `CompleteWizardStep` ("Complete"), as shown in Figure 23.

Figure 23: Add a New `WizardStep` to the CreateUserWizard Control (Click to view full-size image)

Click OK to close the `WizardStep` Collection Editor dialog. The new `WizardStep` is evidenced by the CreateUserWizard control's updated declarative markup:

```
<asp:CreateUserWizard ID="NewUserWizard" runat="server"

          ContinueDestinationPageUrl="~/Membership/AdditionalUserInfo.aspx">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:WizardStep runat="server" ID="UserSettings" StepType="Step"

               Title="Your Settings">
          </asp:WizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

Note the new `<asp:WizardStep>` element. We need to add the user interface to collect the new user's home town, homepage, and signature here. You can enter this content in the declarative syntax or through the Designer. To use the Designer, select the "Your Settings" step from the drop-down list in the Smart Tag to see the step in the Designer.

> **NOTE**
>
> Selecting a step through the Smart Tag's drop-down list updates the CreateUserWizard control's `ActiveStepIndex` property, which specifies the index of the starting step. Therefore, if you use this drop-down list to edit the "Your Settings" step in the Designer, be sure to set it back to "Sign Up for Your New Account" so that this step is shown when users first visit the `EnhancedCreateUserWizard.aspx` page.

Create a user interface within the "Your Settings" step that contains three TextBox controls named `HomeTown`, `HomepageUrl`, and `Signature`. After constructing this interface, the CreateUserWizard's declarative markup should look similar to the following:

```
<asp:CreateUserWizard ID="NewUserWizard" runat="server"

          ContinueDestinationPageUrl="~/Membership/AdditionalUserInfo.aspx">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:WizardStep runat="server" ID="UserSettings" StepType="Step"

                    Title="Your Settings">
               <p>
                    <b>Home Town:</b><br />
                    <asp:TextBox ID="HomeTown" runat="server"></asp:TextBox>

               </p>
               <p>
                    <b>Homepage URL:</b><br />
                    <asp:TextBox ID="HomepageUrl" Columns="40" runat="server"></asp:TextBox>

               </p>
               <p>
                    <b>Signature:</b><br />
                    <asp:TextBox ID="Signature" TextMode="MultiLine" Width="95%"

                         Rows="5" runat="server"></asp:TextBox>
               </p>
          </asp:WizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">

          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

Go ahead and visit this page through a browser and create a new user account, specifying values for the home town, homepage, and signature. After completing the `CreateUserWizardStep` the user account is created in the Membership framework and the `CreatedUser` event handler runs, which adds a new row to `UserProfiles`, but with a database `NULL` value for `HomeTown`, `HomepageUrl`, and `Signature`. The values entered for the home town, homepage, and signature are never used. The net result is a new user account with a `UserProfiles` record whose `HomeTown`, `HomepageUrl`, and `Signature` fields have yet to be specified.

We need to execute code after the "Your Settings" step that takes the home town, honepage, and signature values entered by the user and updates the appropriate `UserProfiles` record. Each time the user moves between steps in a Wizard control, the Wizard's `ActiveStepChanged` event fires. We can create an event handler for this event and update the `UserProfiles` table when the "Your Settings" step has completed.

Add an event handler for the CreateUserWizard's `ActiveStepChanged` event and add the following code:

```
Protected Sub NewUserWizard_ActiveStepChanged(ByVal sender As Object, ByVal e As System.EventArgs) Handles
NewUserWizard.ActiveStepChanged
     ' Have we JUST reached the Complete step?
     If NewUserWizard.ActiveStep.Title = "Complete" Then
          Dim UserSettings As WizardStep = CType(NewUserWizard.FindControl("UserSettings"),WizardStep)

          ' Programmatically reference the TextBox controls
          Dim HomeTown As TextBox = CType(UserSettings.FindControl("HomeTown"), TextBox)
          Dim HomepageUrl As TextBox = CType(UserSettings.FindControl("HomepageUrl"), TextBox)
          Dim Signature As TextBox = CType(UserSettings.FindControl("Signature"), TextBox)

          ' Update the UserProfiles record for this user
          ' Get the UserId of the just-added user
          Dim newUser As MembershipUser = Membership.GetUser(NewUserWizard.UserName)
          Dim newUserId As Guid = CType(newUser.ProviderUserKey, Guid)

          ' Insert a new record into UserProfiles
          Dim connectionString As String =
ConfigurationManager.ConnectionStrings("SecurityTutorialsConnectionString").ConnectionString

          Dim updateSql As String = "UPDATE UserProfiles SET HomeTown = @HomeTown, HomepageUrl
               = @HomepageUrl, Signature = @Signature WHERE UserId = @UserId"

          Using myConnection As New SqlConnection(connectionString)
               myConnection.Open()
               Dim myCommand As New SqlCommand(updateSql, myConnection)
               myCommand.Parameters.AddWithValue("@HomeTown", HomeTown.Text.Trim())
               myCommand.Parameters.AddWithValue("@HomepageUrl", HomepageUrl.Text.Trim())
               myCommand.Parameters.AddWithValue("@Signature", Signature.Text.Trim())

               myCommand.Parameters.AddWithValue("@UserId", newUserId)
               myCommand.ExecuteNonQuery()
               myConnection.Close()
          End Using
     End If
End Sub
```

The above code starts by determining if we have just reached the "Complete" step. Since the "Complete" step occurs immediately after the "Your Settings" step, then when the visitor reaches "Complete" step that means she just finished the "Your Settings" step.

In such a case, we need to programmatically reference the TextBox controls within the `UserSettings WizardStep`. This is accomplished by first using the `FindControl` method to programmatically referencing the `UserSettings WizardStep`, and then again to reference the TextBoxes from within the `WizardStep`. Once the TextBoxes have been referenced, we're ready to execute the `UPDATE` statement. The `UPDATE` statement has the same number of parameters as the `INSERT` statement in the `CreatedUser` event handler, but here we use the home town, homepage, and signature values supplied by the user.

With this event handler in place, visit the `EnhancedCreateUserWizard.aspx` page through a browser and create a new user account specifying values for the home town, homepage, and signature. After creating the new account you should be redirected to the `AdditionalUserInfo.aspx` page, where the just-entered home town, homepage, and signature information is displayed.

NOTE

Our website currently has two pages from which a visitor can create a new account: `CreatingUserAccounts.aspx` and `EnhancedCreateUserWizard.aspx`. The website's sitemap and login page point to the `CreatingUserAccounts.aspx` page, but the `CreatingUserAccounts.aspx` page does not prompt the user for their home town, homepage, and signature information and does not add a corresponding row to `UserProfiles`. Therefore, either update the `CreatingUserAccounts.aspx` page so that it offers this functionality or update the sitemap and login page to reference `EnhancedCreateUserWizard.aspx` instead of `CreatingUserAccounts.aspx`. If you choose the latter option, be sure to update the `Membership` folder's `Web.config` file so as to allow anonymous users access to the `EnhancedCreateUserWizard.aspx` page.

Summary

In this tutorial we looked at techniques for modeling data that is related to user accounts within the Membership framework. In particular, we looked at modeling entities that share a one-to-many relationship with user accounts as well as data that shares a one-to-one relationship. Furthermore, we saw how this related information could be displayed, inserted, and updated, with some examples using the SqlDataSource control and others using ADO.NET code.

This tutorial completes our look at user accounts. Starting with the next tutorial we will turn our attention to roles. Over the next several tutorials we will look at the Roles framework, see how to create new roles, how to assign roles to users, how to determine what roles a user belongs to, and how to apply role-based authorization.

Happy Programming!

by Scott Mitchell

Download Code or Download PDF

This tutorial examines the steps necessary for configuring the Roles framework. Following that, we will build web pages to create and delete roles.

Introduction

In the *User-Based Authorization* tutorial we looked at using URL authorization to restrict certain users from a set of pages and explored declarative and programmatic techniques for adjusting an ASP.NET page's functionality based on the visiting user. Granting permission for page access or functionality on a user-by-user basis, however, can become a maintenance nightmare in scenarios where there are many user accounts or when users' privileges change often. Any time a user gains or loses authorization to perform a particular task, the administrator needs to update the appropriate URL authorization rules, declarative markup, and code.

It usually helps to classify users into groups or *roles* and then to apply permissions on a role-by-role basis. For example, most web applications have a certain set of pages or tasks that are reserved only for administrative users. Using the techniques learned in the *User-Based Authorization* tutorial, we would add the appropriate URL authorization rules, declarative markup, and code to allow the specified user accounts to perform administrative tasks. But if a new administrator was added or if an existing administrator needed to have her administration rights revoked, we would have to return and update the configuration files and web pages. With roles, however, we could create a role called Administrators and assign those trusted users to the Administrators role. Next, we would add the appropriate URL authorization rules, declarative markup, and code to allow the Administrators role to perform the various administrative tasks. With this infrastructure in place, adding new administrators to the site or removing existing ones is as simple as including or removing the user from the Administrators role. No configuration, declarative markup, or code changes are necessary.

ASP.NET offers a Roles framework for defining roles and associating them with user accounts. With the Roles framework we can create and delete roles, add users to or remove users from a role, determine the set of users that belong to a particular role, and tell whether a user belongs to a particular role. Once the Roles framework has been configured, we can limit access to pages on a role-by-role basis through URL authorization rules and show or hide additional information or functionality on a page based on the currently logged on user's roles.

This tutorial examines the steps necessary for configuring the Roles framework. Following that, we will build web pages to create and delete roles. In the *Assigning Roles to Users* tutorial we will look at how to add and remove users from roles. And in the *Role-Based Authorization* tutorial we will see how to limit access to pages on a role-by-role basis along with how to adjust page functionality depending on the visiting user's role. Let's get started!

Step 1: Adding New ASP.NET Pages

In this tutorial and the next two we will be examining various roles-related functions and capabilities. We will need a series of ASP.NET pages to implement the topics examined throughout these tutorials. Let's create these pages and update the site map.

Start by creating a new folder in the project named `Roles`. Next, add four new ASP.NET pages to the `Roles` folder, linking each page with the `Site.master` master page. Name the pages:

- `ManageRoles.aspx`
- `UsersAndRoles.aspx`
- `CreateUserWizardWithRoles.aspx`
- `RoleBasedAuthorization.aspx`

At this point your project's Solution Explorer should look similar to the screen shot shown in Figure 1.

Figure 1: Four New Pages Have Been Added to the `Roles` Folder (Click to view full-size image)

Each page should, at this point, have the two Content controls, one for each of the master page's ContentPlaceHolders: `MainContent` and `LoginContent`.

```
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent"Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="LoginContent"Runat="Server">
</asp:Content>
```

Recall that the `LoginContent` ContentPlaceHolder's default markup displays a link to log on or log off the site, depending on whether the user is authenticated. The presence of the `Content2` Content control in the ASP.NET page, however, overrides the master page's default markup. As we discussed in *An Overview of Forms Authentication* tutorial, overriding the default markup is useful in pages where we do not want to display login-related options in the left column.

For these four pages, however, we want to show the master page's default markup for the `LoginContent` ContentPlaceHolder. Therefore, remove the declarative markup for the `Content2` Content control. After doing so, each of the four page's markup should contain just one Content control.

Finally, let's update the site map (`Web.sitemap`) to include these new web pages. Add the following XML after the `<siteMapNode>` we added for the Membership tutorials.

```
<siteMapNode title="Roles">
 <siteMapNode url="~/Roles/ManageRoles.aspx" title="Manage Roles"/>
 <siteMapNode url="~/Roles/UsersAndRoles.aspx" title="Users and Roles" />
 <siteMapNode url="~/Roles/CreateUserWizardWithRoles.aspx" title="Create Account (with Roles)" />
 <siteMapNode url="~/Roles/RoleBasedAuthorization.aspx" title="Role-Based Authorization" />
</siteMapNode>
```

With the site map updated, visit the site through a browser. As Figure 2 shows, the navigation on the left now includes items for the Roles tutorials.

Figure 2: Four New Pages Have Been Added to the `Roles` Folder (Click to view full-size image)

Step 2: Specifying and Configuring the Roles Framework Provider

Like the Membership framework, the Roles framework is built atop the provider model. As discussed in the *Security Basics and ASP.NET Support* tutorial, the .NET Framework ships with three built-in Roles providers: `AuthorizationStoreRoleProvider`, `WindowsTokenRoleProvider`, and `SqlRoleProvider`. This tutorial series focuses on the `SqlRoleProvider`, which uses a Microsoft SQL Server database as the role store.

Underneath the covers the Roles framework and `SqlRoleProvider` work just like the Membership framework and `SqlMembershipProvider`. The .NET Framework contains a `Roles` class that serves as the API to the Roles framework. The `Roles` class has static methods like `CreateRole`, `DeleteRole`, `GetAllRoles`, `AddUserToRole`, `IsUserInRole`, and so forth. When one of these methods is invoked, the `Roles` class delegates the call to the configured provider. The `SqlRoleProvider` works with the role-specific tables (`aspnet_Roles` and `aspnet_UsersInRoles`) in response.

In order to use the `SqlRoleProvider` provider in our application, we need to specify what database to use as the store. The `SqlRoleProvider` expects the specified role store to have certain database tables, views, and stored procedures. These requisite database objects can be added using the `aspnet_regsql.exe` tool. At this point we already have a database with the schema necessary for the `SqlRoleProvider`. Back in the *Creating the Membership Schema in SQL Server* tutorial we created a database named `SecurityTutorials.mdf` and used `aspnet_regsql.exe` to add the application services, which included the database objects required by the `SqlRoleProvider`. Therefore we just need to tell the Roles framework to enable role support and to use the `SqlRoleProvider` with the `SecurityTutorials.mdf` database as the role store.

The Roles framework is configured via the `<roleManager>` element in the application's `Web.config` file. By default, role support is disabled. To enable it, you must set the `<roleManager>` element's `enabled` attribute to `true` like so:

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 ... Additional configuration markup removed for brevity ...

 <roleManager enabled="true" />
 <system.web>
</configuration>
```

By default, all web applications have a Roles provider named `AspNetSqlRoleProvider` of type `SqlRoleProvider`. This default provider is registered in `machine.config` (located at `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\CONFIG`):

```
<roleManager>
 <providers>
 <add name="AspNetSqlRoleProvider"
 connectionStringName="LocalSqlServer"
 applicationName="/"
 type="System.Web.Security.SqlRoleProvider,
 System.Web, Version=2.0.0.0, Culture=neutral, PublicKeyToken=b03f5f7f11d50a3a"/>
 </providers>
</roleManager>
```

The provider's `connectionStringName` attribute specifies the role store that is used. The `AspNetSqlRoleProvider` provider sets this attribute to `LocalSqlServer`, which is also defined in `machine.config` and points, by default, to a SQL Server 2005 Express Edition database in the `App_Data` folder named `aspnet.mdf`.

Consequently, if we simply enable the Roles framework without specifying any provider information in our application's `Web.config` file, the application uses the default registered Roles provider, `AspNetSqlRoleProvider`. If the `~/App_Data/aspnet.mdf` database does not exist, the ASP.NET runtime will automatically create it and add the application services schema. However, we don't want to use the `aspnet.mdf` database; rather, we want to use the `SecurityTutorials.mdf` database that we have already created and added the application services schema to. This modification can be accomplished in one of two ways:

- **Specify a value for the `LocalSqlServer` connection string name in `Web.config`.** By overwriting the `LocalSqlServer` connection string name value in `Web.config`, we can use the default registered Roles provider (`AspNetSqlRoleProvider`) and have it correctly work with the `SecurityTutorials.mdf` database. For more information on this technique, see Scott Guthrie's blog post, Configuring ASP.NET 2.0 Application Services to Use SQL Server 2000 or SQL Server 2005.
- **Add a new registered provider of type `SqlRoleProvider` and configure its `connectionStringName` setting to point to the `SecurityTutorials.mdf` database.** This is the approach I recommended and used in the *Creating the Membership Schema in SQL Server* tutorial, and it is the approach I will use in this tutorial as well.

Add the following Roles configuration markup to the `Web.config` file. This markup registers a new provider named `SecurityTutorialsSqlRoleProvider`.

```
<?xml version="1.0"?>
<configuration>
 <connectionStrings>
 <add name="SecurityTutorialsConnectionString"
 connectionString="..."/>
 </connectionStrings>

 <system.web>
 ... Additional configuration markup removed for brevity ...

 <roleManager enabled="true" defaultProvider="SecurityTutorialsSqlRoleProvider">
 <providers>
 <add name="SecurityTutorialsSqlRoleProvider"
 type="System.Web.Security.SqlRoleProvider"
 applicationName="SecurityTutorials"
 connectionStringName="SecurityTutorialsConnectionString" />
 </providers>
 </roleManager>
 <system.web>
</configuration>
```

The above markup defines the `SecurityTutorialsSqlRoleProvider` as the default provider (via the `defaultProvider` attribute in the `<roleManager>` element). It also sets the `SecurityTutorialsSqlRoleProvider`'s `applicationName` setting to `SecurityTutorials`, which is the same `applicationName` setting used by the Membership provider (`SecurityTutorialsSqlMembershipProvider`). While not shown here, the `<add>` element for the `SqlRoleProvider` may also contain a `commandTimeout` attribute to specify the database timeout duration, in seconds. The default value is 30.

With this configuration markup in place, we are ready to start using role functionality within our application.

> **NOTE**
> The above configuration markup illustrates using the < `roleManager` > element's `enabled` and `defaultProvider` attributes. There are a number of other attributes that affect how the Roles framework associates role information on a user-by-user basis. We will examine these settings in the *Role-Based Authorization* tutorial.

Step 3: Examining the Roles API

The Roles framework's functionality is exposed via the `Roles` class, which contains thirteen static methods for performing role-based operations. When we look at creating and deleting roles in Steps 4 and 6 we will use the `CreateRole` and `DeleteRole` methods, which add or remove a role from the system.

To get a list of all of the roles in the system, use the `GetAllRoles` method (see Step 5). The `RoleExists` method returns a Boolean value indicating whether a specified role exists.

In the next tutorial we will examine how to associate users with roles. The `Roles` class's `AddUserToRole`, `AddUserToRoles`, `AddUsersToRole`, and `AddUsersToRoles` methods add one or more users to one or more roles. To remove users from roles, use the `RemoveUserFromRole`, `RemoveUserFromRoles`, `RemoveUsersFromRole`, or `RemoveUsersFromRoles` methods.

In the *Role-Based Authorization* tutorial we will look at ways to programmatically show or hide functionality based on the currently logged in user's role. To accomplish this, we can use the `Role` class's `FindUsersInRole`, `GetRolesForUser`, `GetUsersInRole`, or `IsUserInRole` methods.

> **NOTE**
> Keep in mind that any time one of these methods is invoked, the `Roles` class delegates the call to the configured provider. In our case, this means that the call is being sent to the `SqlRoleProvider`. The `SqlRoleProvider` then performs the appropriate database operation based on the invoked method. For example, the code `Roles.CreateRole("Administrators")` results in the `SqlRoleProvider` executing the `aspnet_Roles_CreateRole` stored procedure, which inserts a new record into the `aspnet_Roles` table named Administrators .

The remainder of this tutorial looks at using the `Roles` class's `CreateRole`, `GetAllRoles`, and `DeleteRole` methods to manage the roles in the system.

Step 4: Creating New Roles

Roles offer a way to arbitrarily group users, and most commonly this grouping is used for a more convenient way to apply authorization rules. But in order to use roles as an authorization mechanism we first need to define what roles exist in the application. Unfortunately, ASP.NET does not include a CreateRoleWizard control. In order to add new roles we need to create a suitable user interface and invoke the Roles API ourselves. The good news is that this is very easy to accomplish.

NOTE

While there is no CreateRoleWizard Web control, there is the ASP.NET Web Site Administration Tool, which is a local ASP.NET application designed to assist with viewing and managing your web application's configuration. However, I am not a big fan of the ASP.NET Web Site Administration Tool for two reasons. First, it is a bit buggy and the user experience leaves a lot to be desired. Second, the ASP.NET Web Site Administration Tool is designed to only work locally, meaning that you will have to build your own role management web pages if you need to manage roles on a live site remotely. For these two reasons, this tutorial and the next will focus on building the necessary role management tools in a web page rather than relying on the ASP.NET Web Site Administration Tool.

Open the `ManageRoles.aspx` page in the `Roles` folder and add a TextBox and a Button Web control to the page. Set the TextBox control's `ID` property to `RoleName` and the Button's `ID` and `Text` properties to `CreateRoleButton` and Create Role, respectively. At this point, your page's declarative markup should look similar to the following:

```
<b>Create a New Role: </b>
<asp:TextBox ID="RoleName" runat="server"></asp:TextBox>
<br />
<asp:Button ID="CreateRoleButton" runat="server" Text="Create Role" />
```

Next, double-click the `CreateRoleButton` Button control in the Designer to create a `Click` event handler and then add the following code:

```
protected void CreateRoleButton_Click(object sender, EventArgs e)
{
    string newRoleName = RoleName.Text.Trim();

    if (!Roles.RoleExists(newRoleName))
        // Create the role
        Roles.CreateRole(newRoleName);

    RoleName.Text = string.Empty;
}
```

The above code starts by assigning the trimmed role name entered in the `RoleName` TextBox to the `newRoleName` variable. Next, the `Roles` class's `RoleExists` method is called to determine if the role `newRoleName` already exists in the system. If the role does not exist, it is created via a call to the `CreateRole` method. If the `CreateRole` method is passed a role name that already exists in the system, a `ProviderException` exception is thrown. This is why the code first checks to ensure that the role does not already exist in the system before calling `CreateRole`. The `Click` event handler concludes by clearing out the `RoleName` TextBox's `Text` property.

NOTE

You may be wondering what will happen if the user doesn't enter any value into the `RoleName` TextBox. If the value passed into the `CreateRole` method is `null` or an empty string, an exception is raised. Likewise, if the role name contains a comma an exception is raised. Consequently, the page should contain validation controls to ensure that the user enters a role and that it does not contain any commas. I leave as an exercise for the reader.

Let's create a role named Administrators. Visit the `ManageRoles.aspx` page through a browser, type in Administrators into the textbox (see Figure 3), and then click the Create Role button.

Figure 3: Create an Administrators Role (Click to view full-size image)

What happens? A postback occurs, but there's no visual cue that the role has actually been added to the system. We will update this page in Step 5 to include visual feedback. For now, however, you can verify that the role was created by going to the `SecurityTutorials.mdf` database and displaying the data from the `aspnet_Roles` table. As Figure 4 shows, the `aspnet_Roles` table contains a record for the just-added Administrators roles.

Figure 4: The `aspnet_Roles` Table has a Row for the Administrators (Click to view full-size image)

Step 5: Displaying the Roles in the System

Let's augment the `ManageRoles.aspx` page to include a list of the current roles in the system. To accomplish this, add a GridView control to the page and set its `ID` property to `RoleList`. Next, add a method to the page's code-behind class named `DisplayRolesInGrid` using the following code:

```
private void DisplayRolesInGrid()
{
    RoleList.DataSource = Roles.GetAllRoles();
    RoleList.DataBind();
}
```

The `Roles` class's `GetAllRoles` method returns all of the roles in the system as an array of strings. This string array is then bound to the GridView. In order to bind the list of roles to the GridView when the page is first loaded, we need to call the `DisplayRolesInGrid` method from the page's `Page_Load` event handler. The following code calls this method when the page is first visited, but not on subsequent postbacks.

```
protected void Page_Load(object sender, EventArgs e)
{
    if (!Page.IsPostBack)
    DisplayRolesInGrid();
}
```

With this code in place, visit the page through a browser. As Figure 5 shows, you should see a grid with a single column labeled Item. The grid includes a row for the Administrators role we added in Step 4.

Figure 5: The GridView Displays the Roles in a Single Column (Click to view full-size image)

The GridView displays a lone column labeled Item because the GridView's `AutoGenerateColumns` property is set to True (the default), which causes the GridView to automatically create a column for each property in its `DataSource`. An array has a single property that represents the elements in the array, hence the single column in the GridView.

When displaying data with a GridView, I prefer to explicitly define my columns rather than have them implicitly generated by the GridView. By explicitly defining the columns it is much easier to format the data, rearrange the columns, and perform other common tasks. Therefore, let's update the GridView's declarative markup so that its columns are explicitly defined.

Start by setting the GridView's `AutoGenerateColumns` property to False. Next, add a TemplateField to the grid, set its `HeaderText` property to Roles, and configure its `ItemTemplate` so that it displays the contents of the array. To accomplish this, add a Label Web control named `RoleNameLabel` to the `ItemTemplate` and bind its `Text` property to `Container.DataItem`.

These properties and the `ItemTemplate`'s contents can be set declaratively or through the GridView's Fields dialog box and Edit Templates interface. To reach the Fields dialog box, click the Edit Columns link in the GridView's Smart Tag. Next, uncheck the Auto-generate fields checkbox to set the `AutoGenerateColumns` property to False, and add a TemplateField to the GridView, setting its `HeaderText` property to Role. To define the `ItemTemplate`'s contents, choose the Edit Templates option from the GridView's Smart Tag. Drag a Label Web control onto the `ItemTemplate`, set its `ID` property to `RoleNameLabel`, and configure its databinding settings so that its `Text` property is bound to `Container.DataItem`.

Regardless of what approach you use, the GridView's resulting declarative markup should look similar to the following when you are done.

```
<asp:GridView ID="RoleList" runat="server" AutoGenerateColumns="false">
 <Columns>
 <asp:TemplateField HeaderText="Role">
 <ItemTemplate>
 <asp:Label runat="server" ID="RoleNameLabel" Text='<%# Container.DataItem %>' />
 </ItemTemplate>
 </asp:TemplateField>
 </Columns>
</asp:GridView>
```

NOTE

The array's contents are displayed using the databinding syntax `<%# Container.DataItem %>`. A thorough description of why this syntax is used when displaying the contents of an array bound to the GridView is beyond the scope of this tutorial. For more information on this matter, refer to Binding a Scalar Array to a Data Web Control.

Currently, the `RoleList` GridView is only bound to the list of roles when the page is first visited. We need to refresh the grid whenever a new role is added. To accomplish this, update the `CreateRoleButton` Button's `Click` event handler so that it calls the `DisplayRolesInGrid` method if a new role is created.

```
protected void CreateRoleButton_Click(object sender, EventArgs e)
{
    string newRoleName = RoleName.Text.Trim();

    if (!Roles.RoleExists(newRoleName))
    {
        // Create the role
        Roles.CreateRole(newRoleName);

        // Refresh the RoleList Grid
        DisplayRolesInGrid();
    }

    RoleName.Text = string.Empty;
}
```

Now when the user adds a new role the `RoleList` GridView shows the just-added role on postback, providing visual feedback that the role was successfully created. To illustrate this, visit the `ManageRoles.aspx` page through a browser and add a role named Supervisors. Upon clicking the Create Role button, a postback will ensue and the grid will update to include Administrators as well as the new role, Supervisors.

Figure 6: The Supervisors Role has Been Added (Click to view full-size image)

Step 6: Deleting Roles

At this point a user can create a new role and view all existing roles from the `ManageRoles.aspx` page. Let's allow users to also delete roles. The `Roles.DeleteRole` method has two overloads:

- `DeleteRole(roleName)` - deletes the role *roleName*. An exception is thrown if the role contains one or more members.
- `DeleteRole(roleName, throwOnPopulatedRole)` - deletes the role *roleName*. If *throwOnPopulateRole* is `true`, then an exception is thrown if the role contains one or more members. If *throwOnPopulateRole* is `false`, then the role is deleted whether it contains any members or not. Internally, the `DeleteRole(roleName)` method calls `DeleteRole(roleName, true)`.

The `DeleteRole` method will also throw an exception if *roleName* is `null` or an empty string or if *roleName* contains a comma. If *roleName* does not exist in the system, `DeleteRole` fails silently, without raising an exception.

Let's augment the GridView in `ManageRoles.aspx` to include a Delete button that, when clicked, deletes the selected role. Start by adding a Delete button to the GridView by going to the Fields dialog box and adding a Delete button, which is located under the CommandField option. Make the Delete button the far left column and set its `DeleteText` property to Delete Role .

Figure 7: Add a Delete Button to the `RoleList` GridView (Click to view full-size image)

After adding the Delete button, your GridView's declarative markup should look similar to the following:

```
<asp:GridView ID="RoleList" runat="server" AutoGenerateColumns="False">
 <Columns>
 <asp:CommandField DeleteText="Delete Role" ShowDeleteButton="True"/>
 <asp:TemplateField HeaderText="Role">
 <ItemTemplate>
 <asp:Label runat="server" ID="RoleNameLabel" Text='<%# Container.DataItem %>' />
 </ItemTemplate>
 </asp:TemplateField>
 </Columns>
</asp:GridView>
```

Next, create an event handler for the GridView's `RowDeleting` event. This is the event that is raised on postback when the Delete Role button is clicked. Add the following code to the event handler.

```
protected void RoleList_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
    // Get the RoleNameLabel
    Label RoleNameLabel = RoleList.Rows[e.RowIndex].FindControl("RoleNameLabel") as Label;

    // Delete the role
    Roles.DeleteRole(RoleNameLabel.Text, false);

    // Rebind the data to the RoleList grid
    DisplayRolesInGrid();
}
```

The code starts by programmatically referencing the `RoleNameLabel` Web control in the row whose Delete Role button was clicked. The `Roles.DeleteRole` method is then invoked, passing in the `Text` of the `RoleNameLabel` and `false`, thereby deleting the role regardless of whether there are any users associated with the role. Finally, the `RoleList` GridView is refreshed so that the just-deleted role no longer appears in the grid.

NOTE

The Delete Role button does not require any sort of confirmation from the user before deleting the role. One of the easiest ways to confirm an action is through a client-side confirm dialog box. For more information on this technique, see Adding Client-Side Confirmation When Deleting.

Summary

Many web applications have certain authorization rules or page-level functionality that is only available to certain classes of users. For example, there may be a set of web pages that only administrators can access. Rather than defining these authorization rules on a user-by-user basis, oftentimes it is more useful to define the rules based on a role. That is, rather than explicitly allowing users Scott and Jisun to access the administrative web pages, a more maintainable approach is to permit members of the Administrators role to access these pages, and then to denote Scott and Jisun as users belonging to the Administrators role.

The Roles framework makes it easy to create and manage roles. In this tutorial we examined how to configure the Roles framework to use the `SqlRoleProvider`, which uses a Microsoft SQL Server database as the role store. We also created a web page that lists the existing roles in the system and allows for new roles to be created and existing ones to be deleted. In subsequent tutorials we will see how to assign users to roles and how to apply role-based authorization.

Happy Programming!

Assigning Roles to Users (C#)

2/20/2020 • 28 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will build two ASP.NET pages to assist with managing what users belong to what roles. The first page will include facilities to see what users belong to a given role, what roles a particular user belongs to, and the ability to assign or remove a particular user from a particular role. In the second page we will augment the CreateUserWizard control so that it includes a step to specify what roles the newly created user belongs to. This is useful in scenarios where an administrator is able to create new user accounts.

Introduction

The previous tutorial examined the Roles framework and the `SqlRoleProvider`; we saw how to use the `Roles` class to create, retrieve, and delete roles. In addition to creating and deleting roles, we need to be able to assign or remove users from a role. Unfortunately, ASP.NET does not ship with any Web controls for managing what users belong to what roles. Instead, we must create our own ASP.NET pages to manage these associations. The good news is that adding and removing users to roles is quite easy. The `Roles` class contains a number of methods for adding one or more users to one or more roles.

In this tutorial we will build two ASP.NET pages to assist with managing what users belong to what roles. The first page will include facilities to see what users belong to a given role, what roles a particular user belongs to, and the ability to assign or remove a particular user from a particular role. In the second page we will augment the CreateUserWizard control so that it includes a step to specify what roles the newly created user belongs to. This is useful in scenarios where an administrator is able to create new user accounts.

Let's get started!

Listing What Users Belong To What Roles

The first order of business for this tutorial is to create a web page from which users can be assigned to roles. Before we concern ourselves with how to assign users to roles, let's first concentrate on how to determine what users belong to what roles. There are two ways to display this information: "by role" or "by user." We could allow the visitor to select a role and then show them all of the users that belong to the role (the "by role" display), or we could prompt the visitor to select a user and then show them the roles assigned to that user (the "by user" display).

The "by role" view is useful in circumstances where the visitor wants to know the set of users that belong to a particular role; the "by user" view is ideal when the visitor needs to know a particular user's role(s). Let's have our page include both "by role" and "by user" interfaces.

We will start with creating the "by user" interface. This interface will consist of a drop-down list and a list of checkboxes. The drop-down list will be populated with the set of users in the system; the checkboxes will enumerate the roles. Selecting a user from the drop-down list will check those roles the user belongs to. The person visiting the page can then check or uncheck the checkboxes to add or remove the selected user from the corresponding roles.

> **NOTE**
> Using a drop-down list to list the user accounts is not an ideal choice for websites where there may be hundreds of user accounts. A drop-down list is designed to allow a user to pick one item from a relatively short list of options. It quickly becomes unwieldy as the number of list items grows. If you are building a website that will have potentially large numbers of user accounts, you may want to consider using an alternative user interface, such as a pageable GridView or a filterable interface that lists prompts the visitor to choose a letter and then only shows those users whose username starts with the selected letter.

Step 1: Building the "By User" User Interface

Open the `UsersAndRoles.aspx` page. At the top of the page, add a Label Web control named `ActionStatus` and clear out its `Text` property. We will use this Label to provide feedback on the actions performed, displaying messages like, "User Tito has been added to the Administrators role," or "User Jisun has been removed from the Supervisors role." In order to make these messages stand out, set the Label's `CssClass` property to "Important".

```
<p align="center">

     <asp:Label ID="ActionStatus" runat="server" CssClass="Important"></asp:Label>
</p>
```

Next, add the following CSS class definition to the `Styles.css` stylesheet:

```
.Important
{
     font-size: large;
     color: Red;
}
```

This CSS definition instructs the browser to display the Label using a large, red font. Figure 1 shows this effect through the Visual Studio Designer.

Figure 1: The Label's `CssClass` Property Results in a Large, Red Font (Click to view full-size image)

Next, add a DropDownList to the page, set its `ID` property to `UserList`, and set its `AutoPostBack` property to True. We will use this DropDownList to list all of the users in the system. This DropDownList will be bound to a collection of MembershipUser objects. Because we want the DropDownList to display the UserName property of the MembershipUser object (and use it as the value of the list items), set the DropDownList's `DataTextField` and `DataValueField` properties to "UserName".

Underneath the DropDownList, add a Repeater named `UsersRoleList`. This Repeater will list all of the roles in the system as a series of checkboxes. Define the Repeater's `ItemTemplate` using the following declarative markup:

```
<asp:Repeater ID="UsersRoleList" runat="server">
     <ItemTemplate>
          <asp:CheckBox runat="server" ID="RoleCheckBox" AutoPostBack="true"

               Text='<%# Container.DataItem %>' />
          <br />
     </ItemTemplate>
</asp:Repeater>
```

The `ItemTemplate` markup includes a single CheckBox Web control named `RoleCheckBox`. The CheckBox's `AutoPostBack` property is set to True and the `Text` property is bound to `Container.DataItem`. The reason the databinding syntax is simply `Container.DataItem` is because the Roles framework returns the list of role names as a string array, and it is this string array that we will be binding to the Repeater. A thorough description of why this syntax is used to display the contents of an array bound to a data Web control is beyond the scope of this tutorial. For more information on this matter, refer to Binding a Scalar Array to a Data Web Control.

At this point your "by user" interface's declarative markup should look similar to the following:

```
<h3>Manage Roles By User</h3>

<p>
     <b>Select a User:</b>
     <asp:DropDownList ID="UserList" runat="server" AutoPostBack="True"
          DataTextField="UserName" DataValueField="UserName">

     </asp:DropDownList>
</p>
<p>
     <asp:Repeater ID="UsersRoleList" runat="server">
          <ItemTemplate>
               <asp:CheckBox runat="server" ID="RoleCheckBox" AutoPostBack="true"

                    Text='<%# Container.DataItem %>' />
               <br />
          </ItemTemplate>
     </asp:Repeater>
</p>
```

We are now ready to write the code to bind the set of user accounts to the DropDownList and the set of roles to the Repeater. In the page's code-behind class, add a method named `BindUsersToUserList` and another named `BindRolesList`, using the following code:

```
private void BindUsersToUserList()
{
     // Get all of the user accounts
     MembershipUserCollection users = Membership.GetAllUsers();
     UserList.DataSource = users;
     UserList.DataBind();
}

private void BindRolesToList()
{
     // Get all of the roles
     string[] roles = Roles.GetAllRoles();
     UsersRoleList.DataSource = roles;
     UsersRoleList.DataBind();
}
```

The `BindUsersToUserList` method retrieves all of the user accounts in the system via the `Membership.GetAllUsers` method. This returns a `MembershipUserCollection` object, which is a collection of `MembershipUser` instances. This collection is then bound to the `UserList` DropDownList. The `MembershipUser` instances that makeup the collection contain a variety of properties, like `UserName`, `Email`, `CreationDate`, and `IsOnline`. In order to instruct the DropDownList to display the value of the `UserName` property, ensure that the `UserList` DropDownList's `DataTextField` and `DataValueField` properties have been set to "UserName".

> **NOTE**
>
> The `Membership.GetAllUsers` method has two overloads: one that accepts no input parameters and returns all of the users, and one that takes in integer values for the page index and page size, and returns only the specified subset of the users. When there are large amounts of user accounts being displayed in a pageable user interface element, the second overload can be used to more efficiently page through the users since it returns just the precise subset of user accounts rather than all of them.

The `BindRolesToList` method starts by calling the `Roles` class's `GetAllRoles` method, which returns a string array containing the roles in the system. This string array is then bound to the Repeater.

Finally, we need to call these two methods when the page is first loaded. Add the following code to the `Page_Load` event handler:

```
protected void Page_Load(object sender, EventArgs e)
{
    if (!Page.IsPostBack)
    {
        // Bind the users and roles
        BindUsersToUserList();
        BindRolesToList();
    }
}
```

With this code in place, take a moment to visit the page through a browser; your screen should look similar to Figure 2. All of the user accounts are populated in the drop-down list and, underneath that, each role appears as a checkbox. Because we set the `AutoPostBack` properties of the DropDownList and CheckBoxes to True, changing the selected user or checking or unchecking a role causes a postback. No action is performed, however, because we have yet to write code to handle these actions. We'll tackle these tasks in the next two sections.

Figure 2: The Page Displays the Users and Roles (Click to view full-size image)

Checking the Roles the Selected User Belongs To

When the page is first loaded, or whenever the visitor selects a new user from the drop-down list, we need to update the `UsersRoleList`'s checkboxes so that a given role checkbox is checked only if the selected user belongs to that role. To accomplish this, create a method named `CheckRolesForSelectedUser` with the following code:

```
private void CheckRolesForSelectedUser()
{
     // Determine what roles the selected user belongs to
     string selectedUserName = UserList.SelectedValue;
     string[] selectedUsersRoles = Roles.GetRolesForUser(selectedUserName);

     // Loop through the Repeater's Items and check or uncheck the checkbox as needed

     foreach (RepeaterItem ri in UsersRoleList.Items)
     {
          // Programmatically reference the CheckBox
          CheckBox RoleCheckBox = ri.FindControl("RoleCheckBox") as CheckBox;
          // See if RoleCheckBox.Text is in selectedUsersRoles
          if (selectedUsersRoles.Contains<string>(RoleCheckBox.Text))
               RoleCheckBox.Checked = true;
          else
               RoleCheckBox.Checked = false;
     }
}
```

The above code starts by determining who the selected user is. It then uses the Roles class's `GetRolesForUser(userName)` method to return the specified user's set of roles as a string array. Next, the Repeater's items are enumerated and each item's `RoleCheckBox` CheckBox is programmatically referenced. The CheckBox is checked only if the role it corresponds to is contained within the `selectedUsersRoles` string array.

> **NOTE**
>
> The `selectedUserRoles.Contains<string>(...)` syntax will not compile if you are using ASP.NET version 2.0. The `Contains<string>` method is part of the LINQ library, which is new to ASP.NET 3.5. If you are still using ASP.NET version 2.0, use the `Array.IndexOf<string>` method instead.

The `CheckRolesForSelectedUser` method needs to be called in two cases: when the page is first loaded and whenever the `UserList` DropDownList's selected index is changed. Therefore, call this method from the `Page_Load` event handler (after the calls to `BindUsersToUserList` and `BindRolesToList`). Also, create an event handler for the DropDownList's `SelectedIndexChanged` event and call this method from there.

```
protected void Page_Load(object sender, EventArgs e)
{
     if (!Page.IsPostBack)
     {

          // Bind the users and roles
          BindUsersToUserList();
          BindRolesToList();
          // Check the selected user's roles
          CheckRolesForSelectedUser();
     }
}

...

protected void UserList_SelectedIndexChanged(object sender, EventArgs e)
{
     CheckRolesForSelectedUser();
}
```

With this code in place, you can test the page through the browser. However, since the `UsersAndRoles.aspx` page currently lacks the ability to assign users to roles, no users have roles. We will create the interface for assigning users to roles in a moment, so you can either take my word that this code works and verify that it does so later, or you can manually add users to roles by inserting records into the `aspnet_UsersInRoles` table in order to test this functionality now.

Assigning and Removing Users from Roles

When the visitor checks or unchecks a CheckBox in the `UsersRoleList` Repeater we need to add or remove the selected user from the corresponding role. The CheckBox's `AutoPostBack` property is currently set to True, which causes a postback anytime a CheckBox in the Repeater is checked or unchecked. In short, we need to create an event handler for the CheckBox's `CheckChanged` event. Since the CheckBox is in a Repeater control, we need to manually add the event handler plumbing. Start by adding the event handler to the code-behind class as a `protected` method, like so:

```
protected void RoleCheckBox_CheckChanged(object sender, EventArgs e)
{

}
```

We will return to write the code for this event handler in a moment. But first let's complete the event handling plumbing. From the CheckBox within the Repeater's `ItemTemplate`, add `OnCheckedChanged="RoleCheckBox_CheckChanged"`. This syntax wires the `RoleCheckBox_CheckChanged` event handler to the `RoleCheckBox`'s `CheckedChanged` event.

```
<asp:CheckBox runat="server" ID="RoleCheckBox"
     AutoPostBack="true"
     Text='<%# Container.DataItem %>'
     OnCheckedChanged="RoleCheckBox_CheckChanged" />
```

Our final task is to complete the `RoleCheckBox_CheckChanged` event handler. We need to start by referencing the CheckBox control that raised the event because this CheckBox instance tells us what role was checked or unchecked via its `Text` and `Checked` properties. Using this information along with the UserName of the selected user, we add or remove the user from the role via the `Roles` class's `AddUserToRole` or `RemoveUserFromRole` method.

```
protected void RoleCheckBox_CheckChanged(object sender, EventArgs e)
{
     // Reference the CheckBox that raised this event
     CheckBox RoleCheckBox = sender as CheckBox;

     // Get the currently selected user and role
     string selectedUserName = UserList.SelectedValue;

     string roleName = RoleCheckBox.Text;

     // Determine if we need to add or remove the user from this role
     if (RoleCheckBox.Checked)
     {
          // Add the user to the role
          Roles.AddUserToRole(selectedUserName, roleName);
          // Display a status message
          ActionStatus.Text = string.Format("User {0} was added to role {1}.", selectedUserName, roleName);
     }
     else
     {
          // Remove the user from the role
          Roles.RemoveUserFromRole(selectedUserName, roleName);
          // Display a status message
          ActionStatus.Text = string.Format("User {0} was removed from role {1}.", selectedUserName,
roleName);

     }
}
```

The above code starts by programmatically referencing the CheckBox that raised the event, which is available via the `sender` input parameter. If the CheckBox is checked, the selected user is added to the specified role, otherwise they are removed from the role. In either case, the `ActionStatus` Label displays a message summarizing the action just performed.

Take a moment to test out this page through a browser. Select user Tito and then add Tito to both the Administrators and Supervisors roles.

Figure 3: Tito Has Been Added to the Administrators and Supervisors Roles (Click to view full-size image)

Next, select user Bruce from the drop-down list. There is a postback and the Repeater's CheckBoxes are updated via the `CheckRolesForSelectedUser`. Since Bruce does not yet belong to any roles, the two checkboxes are unchecked. Next, add Bruce to the Supervisors role.

Figure 4: Bruce Has Been Added to the Supervisors Role (Click to view full-size image)

To further verify the functionality of the `CheckRolesForSelectedUser` method, select a user other than Tito or Bruce. Note how the checkboxes are automatically unchecked, denoting that they do not belong to any roles. Return to Tito. Both the Administrators and Supervisors checkboxes should be checked.

Step 2: Building the "By Roles" User Interface

At this point we have completed the "by users" interface and are ready to start tackling the "by roles" interface. The "by roles" interface prompts the user to select a role from a drop-down list and then displays the set of users that belong to that role in a GridView.

Add another DropDownList control to the `UsersAndRoles.aspx` page. Place this one beneath the Repeater control, name it `RoleList`, and set its `AutoPostBack` property to True. Underneath that, add a GridView and name it `RolesUserList`. This GridView will list the users that belong to the selected role. Set the GridView's `AutoGenerateColumns` property to False, add a TemplateField to the grid's `Columns` collection, and set its `HeaderText` property to "Users". Define the TemplateField's `ItemTemplate` so that it displays the value of the databinding expression `Container.DataItem` in the `Text` property of a Label named `UserNameLabel`.

After adding and configuring the GridView, your "by role" interface's declarative markup should look similar to the following:

```
<h3>Manage Users By Role</h3>
<p>
     <b>Select a Role:</b>

     <asp:DropDownList ID="RoleList" runat="server" AutoPostBack="true"></asp:DropDownList>
</p>
<p>      <asp:GridView ID="RolesUserList" runat="server" AutoGenerateColumns="false"

          EmptyDataText="No users belong to this role.">
          <Columns>
               <asp:TemplateField HeaderText="Users">
                    <ItemTemplate>
                         <asp:Label runat="server" id="UserNameLabel"
                              Text='<%# Container.DataItem %>'></asp:Label>

                    </ItemTemplate>
               </asp:TemplateField>
          </Columns>
     </asp:GridView> </p>
```

We need to populate the `RoleList` DropDownList with the set of roles in the system. To accomplish this, update the `BindRolesToList` method so that is binds the string array returned by the `Roles.GetAllRoles` method to the `RolesList` DropDownList (as well as the `UsersRoleList` Repeater).

```
private void BindRolesToList()
{
     // Get all of the roles

     string[] roles = Roles.GetAllRoles();
     UsersRoleList.DataSource = roles;
     UsersRoleList.DataBind();

     RoleList.DataSource = roles;
     RoleList.DataBind();
}
```

The last two lines in the `BindRolesToList` method have been added to bind the set of roles to the `RoleList` DropDownList control. Figure 5 shows the end result when viewed through a browser – a drop-down list populated with the system's roles.

Figure 5: The Roles are Displayed in the `RoleList` DropDownList (Click to view full-size image)

Displaying the Users That Belong To the Selected Role

When the page is first loaded, or when a new role is selected from the `RoleList` DropDownList, we need to display the list of users that belong to that role in the GridView. Create a method named `DisplayUsersBelongingToRole` using the following code:

```
private void DisplayUsersBelongingToRole()
{
     // Get the selected role
     string selectedRoleName = RoleList.SelectedValue;

     // Get the list of usernames that belong to the role
     string[] usersBelongingToRole = Roles.GetUsersInRole(selectedRoleName);

     // Bind the list of users to the GridView
     RolesUserList.DataSource = usersBelongingToRole;
     RolesUserList.DataBind();
}
```

This method starts by getting the selected role from the `RoleList` DropDownList. It then uses the `Roles.GetUsersInRole(roleName)` method to retrieve a string array of the UserNames of the users that belong to that role. This array is then bound to the `RolesUserList` GridView.

This method needs to be called in two circumstances: when the page is initially loaded and when the selected role in the `RoleList` DropDownList changes. Therefore, update the `Page_Load` event handler so that this method is invoked after the call to `CheckRolesForSelectedUser`. Next, create an event handler for the `RoleList`'s `SelectedIndexChanged` event, and call this method from there, too.

```
protected void Page_Load(object sender, EventArgs e)
{
     if (!Page.IsPostBack)
     {
          // Bind the users and roles
          BindUsersToUserList();
          BindRolesToList();

          // Check the selected user's roles
          CheckRolesForSelectedUser();

          // Display those users belonging to the currently selected role
          DisplayUsersBelongingToRole();
     }
}

...

protected void RoleList_SelectedIndexChanged(object sender, EventArgs e)
{
     DisplayUsersBelongingToRole();
}
```

With this code in place, the `RolesUserList` GridView should display those users that belong to the selected role. As Figure 6 shows, the Supervisors role consists of two members: Bruce and Tito.

Figure 6: The GridView Lists Those Users That Belong to the Selected Role (Click to view full-size image)

Removing Users from the Selected Role

Let's augment the `RolesUserList` GridView so that it includes a column of "Remove" buttons. Clicking the "Remove" button for a particular user will remove them from that role.

Start by adding a Delete button field to the GridView. Make this field appear as the left most filed and change its `DeleteText` property from "Delete" (the default) to "Remove".

Figure 7: Add the "Remove" Button to the GridView (Click to view full-size image)

When the "Remove" button is clicked a postback ensues and the GridView's `RowDeleting` event is raised. We need to create an event handler for this event and write code that removes the user from the selected role. Create the event handler and then add the following code:

```
protected void RolesUserList_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
     // Get the selected role
     string selectedRoleName = RoleList.SelectedValue;

     // Reference the UserNameLabel
     Label UserNameLabel = RolesUserList.Rows[e.RowIndex].FindControl("UserNameLabel") as Label;

     // Remove the user from the role
     Roles.RemoveUserFromRole(UserNameLabel.Text, selectedRoleName);

     // Refresh the GridView
     DisplayUsersBelongingToRole();

     // Display a status message
     ActionStatus.Text = string.Format("User {0} was removed from role {1}.", UserNameLabel.Text,
selectedRoleName);
}
```

The code starts by determining the selected role name. It then programmatically references the `UserNameLabel` control from the row whose "Remove" button was clicked in order to determine the UserName of the user to remove. The user is then removed from the role via a call to the `Roles.RemoveUserFromRole` method. The `RolesUserList` GridView is then refreshed and a message is displayed via the `ActionStatus` Label control.

> **NOTE**
>
> The "Remove" button does not require any sort of confirmation from the user before removing the user from the role. I invite you to add some level of user confirmation. One of the easiest ways to confirm an action is through a client-side confirm dialog box. For more information on this technique, see Adding Client-Side Confirmation When Deleting.

Figure 8 shows the page after user Tito has been removed from the Supervisors group.

Figure 8: Alas, Tito is No Longer a Supervisor (Click to view full-size image)

Adding New Users to the Selected Role

Along with removing users from the selected role, the visitor to this page should also be able to add a user to the selected role. The best interface for adding a user to the selected role depends on the number of user accounts you expect to have. If your website will house just a few dozen user accounts or less, you could use a DropDownList here. If there might be thousands of user accounts, you would want to include a user interface that permits the visitor to page through the accounts, search for a particular account, or filter the user accounts in some other fashion.

For this page let's use a very simple interface that works regardless of the number of user accounts in the system. Namely, we will use a TextBox, prompting the visitor to type in the username of the user she wants to add to the selected role. If no user with that name exists, or if the user is already a member of the role, we'll display a message in `ActionStatus` Label. But if the user exists and is not a member of the role, we'll add them to the role and refresh the grid.

Add a TextBox and Button beneath the GridView. Set the TextBox's `ID` to `UserNameToAddToRole` and set the Button's `ID` and `Text` properties to `AddUserToRoleButton` and "Add User to Role", respectively.

```
<p>
    <b>UserName:</b>
    <asp:TextBox ID="UserNameToAddToRole" runat="server"></asp:TextBox>
    <br />
    <asp:Button ID="AddUserToRoleButton" runat="server" Text="Add User to Role" />

</p>
```

Next, create a `Click` event handler for the `AddUserToRoleButton` and add the following code:

```
protected void AddUserToRoleButton_Click(object sender, EventArgs e)
{
     // Get the selected role and username

     string selectedRoleName = RoleList.SelectedValue;
     string userNameToAddToRole = UserNameToAddToRole.Text;

     // Make sure that a value was entered
     if (userNameToAddToRole.Trim().Length == 0)
     {
          ActionStatus.Text = "You must enter a username in the textbox.";
          return;
     }

     // Make sure that the user exists in the system
     MembershipUser userInfo = Membership.GetUser(userNameToAddToRole);
     if (userInfo == null)
     {
          ActionStatus.Text = string.Format("The user {0} does not exist in the system.",
userNameToAddToRole);

          return;
     }

     // Make sure that the user doesn't already belong to this role
     if (Roles.IsUserInRole(userNameToAddToRole, selectedRoleName))
     {
          ActionStatus.Text = string.Format("User {0} already is a member of role {1}.", userNameToAddToRole,
selectedRoleName);
          return;
     }

     // If we reach here, we need to add the user to the role
     Roles.AddUserToRole(userNameToAddToRole, selectedRoleName);

     // Clear out the TextBox
     UserNameToAddToRole.Text = string.Empty;

     // Refresh the GridView
     DisplayUsersBelongingToRole();

     // Display a status message

     ActionStatus.Text = string.Format("User {0} was added to role {1}.", userNameToAddToRole,
selectedRoleName); }
```

The majority of the code in the `Click` event handler performs various validation checks. It ensures that the visitor supplied a username in the `UserNameToAddToRole` TextBox, that the user exists in the system, and that they don't already belong to the selected role. If any of these checks fails, an appropriate message is displayed in `ActionStatus` and the event handler is exited. If all of the checks pass, the user is added to the role via the `Roles.AddUserToRole` method. Following that, the TextBox's `Text` property is cleared out, the GridView is refreshed, and the `ActionStatus` Label displays a message indicating that the specified user was successfully added to the selected role.

NOTE

To ensure that the specified user does not already belong to the selected role, we use the `Roles.IsUserInRole(userName, roleName)` method, which returns a Boolean value indicating whether *userName* is a member of *roleName*. We will use this method again in the next tutorial when we look at role-based authorization.

Visit the page through a browser and select the Supervisors role from the `RoleList` DropDownList. Try entering

an invalid username – you should see a message explaining that the user does not exist in the system.

Figure 9: You Cannot Add a Non-Existent User to a Role (Click to view full-size image)

Now try adding a valid user. Go ahead and re-add Tito to the Supervisors role.

Figure 10: Tito Is Once Again a Supervisor! (Click to view full-size image)

Step 3: Cross-Updating the "By User" and "By Role" Interfaces

The `UsersAndRoles.aspx` page offers two distinct interfaces for managing users and roles. Currently, these two interfaces act independently of one another so it is possible that a change made in one interface will not be reflected immediately in the other. For example, imagine that the visitor to the page selects the Supervisors role from the `RoleList` DropDownList, which lists Bruce and Tito as its members. Next, the visitor selects Tito from the `UserList` DropDownList, which checks the Administrators and Supervisors checkboxes in the `UsersRoleList`

Repeater. If the visitor then unchecks the Supervisor role from the Repeater, Tito is removed from the Supervisors role, but this modification is not reflected in the "by role" interface. The GridView will still show Tito as being a member of the Supervisors role.

To fix this we need to refresh the GridView whenever a role is checked or unchecked from the `UsersRoleList` Repeater. Likewise, we need to refresh the Repeater whenever a user is removed or added to a role from the "by role" interface.

The Repeater in the "by user" interface is refreshed by calling the `CheckRolesForSelectedUser` method. The "by role" interface can be modified in the `RolesUserList` GridView's `RowDeleting` event handler and the `AddUserToRoleButton` Button's `Click` event handler. Therefore, we need to call the `CheckRolesForSelectedUser` method from each of these methods.

```
protected void RolesUserList_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
     ... Code removed for brevity ...

     // Refresh the "by user" interface
     CheckRolesForSelectedUser();
}

protected void AddUserToRoleButton_Click(object sender, EventArgs e)
{
     ... Code removed for brevity ...

     // Refresh the "by user" interface
     CheckRolesForSelectedUser();
}
```

Similarly, the GridView in the "by role" interface is refreshed by calling the `DisplayUsersBelongingToRole` method and the "by user" interface is modified through the `RoleCheckBox_CheckChanged` event handler. Therefore, we need to call the `DisplayUsersBelongingToRole` method from this event handler.

```
protected void RoleCheckBox_CheckChanged(object sender, EventArgs e)
{
     ... Code removed for brevity...

     // Refresh the "by role" interface
     DisplayUsersBelongingToRole();
}
```

With these minor code changes, the "by user" and "by role" interfaces now correctly cross-update. To verify this, visit the page through a browser and select Tito and Supervisors from the `UserList` and `RoleList` DropDownLists, respectively. Note that as you uncheck the Supervisors role for Tito from the Repeater in the "by user" interface, Tito is automatically removed from the GridView in the "by role" interface. Adding Tito back to the Supervisors role from the "by role" interface automatically re-checks the Supervisors checkbox in the "by user" interface.

Step 4: Customizing the CreateUserWizard to Include a "Specify Roles" Step

In the *Creating User Accounts* tutorial we saw how to use the CreateUserWizard Web control to provide an interface for creating a new user account. The CreateUserWizard control can be used in one of two ways:

- As a means for visitors to create their own user account on the site, and
- As a means for administrators to create new accounts

In the first use case, a visitor comes to the site and fills out the CreateUserWizard, entering their information in order to register on the site. In the second case, an administrator creates a new account for another person.

When an account is being created by an administrator for some other person, it might be helpful to allow the administrator to specify what roles the new user account belongs to. In the *Storing Additional User Information* tutorial we saw how to customize the CreateUserWizard by adding additional `WizardSteps`. Let's look at how to add an additional step to the CreateUserWizard in order to specify the new user's roles.

Open the `CreateUserWizardWithRoles.aspx` page and add a CreateUserWizard control named `RegisterUserWithRoles`. Set the control's `ContinueDestinationPageUrl` property to "~/Default.aspx". Because the idea here is that an administrator will be using this CreateUserWizard control to create new user accounts, set the control's `LoginCreatedUser` property to False. This `LoginCreatedUser` property specifies whether the visitor is automatically logged on as the just-created user, and it defaults to True. We set it to False because when an administrator creates a new account we want to keep him signed in as himself.

Next, select the "Add/Remove `WizardSteps`..." option from the CreateUserWizard's Smart Tag and add a new `WizardStep`, setting its `ID` to `SpecifyRolesStep`. Move the `SpecifyRolesStep WizardStep` so that it comes after the "Sign Up for Your New Account" step, but before the "Complete" step. Set the `WizardStep`'s `Title` property to "Specify Roles", its `StepType` property to `Step`, and its `AllowReturn` property to False.

Figure 11: Add the "Specify Roles" `WizardStep` to the CreateUserWizard (Click to view full-size image)

After this change your CreateUserWizard's declarative markup should look like the following:

```
<asp:CreateUserWizard ID="RegisterUserWithRoles" runat="server"
     ContinueDestinationPageUrl="~/Default.aspx" LoginCreatedUser="False">

     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:WizardStep ID="SpecifyRolesStep" runat="server" StepType="Step"

               Title="Specify Roles" AllowReturn="False">
          </asp:WizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>

</asp:CreateUserWizard>
```

In the "Specify Roles" `WizardStep`, add a CheckBoxList named `RoleList`. This CheckBoxList will list the available

roles, enabling the person visiting the page to check what roles the newly created user belongs to.

We are left with two coding tasks: first we must populate the `RoleList` CheckBoxList with the roles in the system; second, we need to add the created user to the selected roles when the user moves from the "Specify Roles" step to the "Complete" step. We can accomplish the first task in the `Page_Load` event handler. The following code programmatically references the `RoleList` CheckBox on the first visit to the page and binds the roles in the system to it.

```
protected void Page_Load(object sender, EventArgs e)
{
     if (!Page.IsPostBack)
     {
          // Reference the SpecifyRolesStep WizardStep
          WizardStep SpecifyRolesStep = RegisterUserWithRoles.FindControl("SpecifyRolesStep") as WizardStep;

          // Reference the RoleList CheckBoxList
          CheckBoxList RoleList = SpecifyRolesStep.FindControl("RoleList") as CheckBoxList;

          // Bind the set of roles to RoleList
          RoleList.DataSource = Roles.GetAllRoles();
          RoleList.DataBind();
     }
}
```

The above code should look familiar. In the *Storing Additional User Information* tutorial we used two `FindControl` statements to reference a Web control from within a custom `WizardStep`. And the code that binds the roles to the CheckBoxList was taken from earlier in this tutorial.

In order to perform the second programming task we need to know when the "Specify Roles" step has been completed. Recall that the CreateUserWizard has an `ActiveStepChanged` event, which fires each time the visitor navigates from one step to another. Here we can determine if the user has reached the "Complete" step; if so, we need to add the user to the selected roles.

Create an event handler for the `ActiveStepChanged` event and add the following code:

```
protected void RegisterUserWithRoles_ActiveStepChanged(object sender, EventArgs e)
{
     // Have we JUST reached the Complete step?
     if (RegisterUserWithRoles.ActiveStep.Title == "Complete")
     {
          // Reference the SpecifyRolesStep WizardStep
          WizardStep SpecifyRolesStep = RegisterUserWithRoles.FindControl("SpecifyRolesStep") as WizardStep;

          // Reference the RoleList CheckBoxList
          CheckBoxList RoleList = SpecifyRolesStep.FindControl("RoleList") as CheckBoxList;

          // Add the checked roles to the just-added user
          foreach (ListItem li in RoleList.Items)

          {
               if (li.Selected)
                    Roles.AddUserToRole(RegisterUserWithRoles.UserName, li.Text);
          }
     }
}
```

If the user has just reached the "Completed" step, the event handler enumerates the items of the `RoleList` CheckBoxList and the just-created user is assigned to the selected roles.

Visit this page through a browser. The first step in the CreateUserWizard is the standard "Sign Up for Your New Account" step, which prompts for the new user's username, password, email, and other key information. Enter the

information to create a new user named Wanda.

Figure 12: Create a New User Named Wanda (Click to view full-size image)

Click the "Create User" button. The CreateUserWizard internally calls the `Membership.CreateUser` method, creating the new user account, and then progresses to the next step, "Specify Roles." Here the system roles are listed. Check the Supervisors checkbox and click Next.

Figure 13: Make Wanda a Member of the Supervisors Role (Click to view full-size image)

Clicking Next causes a postback and updates the `ActiveStep` to the "Complete" step. In the `ActiveStepChanged` event handler, the recently-created user account is assigned to the Supervisors role. To verify this, return to the `UsersAndRoles.aspx` page and select Supervisors from the `RoleList` DropDownList. As Figure 14 shows, the Supervisors are now made up of three users: Bruce, Tito, and Wanda.

Figure 14: Bruce, Tito, and Wanda are All Supervisors (Click to view full-size image)

Summary

The Roles framework offers methods for retrieving information about a particular user's roles and methods for determining what users belong to a specified role. Furthermore, there are a number of methods for adding and removing one or more users to one or more roles. In this tutorial we focused on just two of these methods: `AddUserToRole` and `RemoveUserFromRole`. There are additional variants designed to add multiple users to a single role and to assign multiple roles to a single user.

This tutorial also included a look at extending the CreateUserWizard control to include a `WizardStep` to specify the newly-created user's roles. Such a step could help an administrator streamline the process of creating user accounts for new users.

At this point we have seen how to create and delete roles and how to add and remove users from roles. But we have yet to look at applying role-based authorization. In the following tutorial we will look at defining URL authorization rules on a role-by-role basis, as well as how to limit page-level functionality based on the currently logged in user's roles.

Happy Programming!

Role-Based Authorization (C#)

2/20/2020 • 34 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

This tutorial starts with a look at how the Roles framework associates a user's roles with his security context. It then examines how to apply role-based URL authorization rules. Following that, we will look at using declarative and programmatic means for altering the data displayed and the functionality offered by an ASP.NET page.

Introduction

In the *User-Based Authorization* tutorial we saw how to use URL authorization to specify what users could visit a particular set of pages. With just a little bit of markup in `Web.config`, we could instruct ASP.NET to allow only authenticated users to visit a page. Or we could dictate that only users Tito and Bob were allowed, or indicate that all authenticated users except for Sam were permitted.

In addition to URL authorization, we also looked at declarative and programmatic techniques for controlling the data displayed and the functionality offered by a page based on the user visiting. In particular, we created a page that listed the contents of the current directory. Anyone could visit this page, but only authenticated users could view the files' contents and only Tito could delete the files.

Applying authorization rules on a user-by-user basis can grow into a bookkeeping nightmare. A more maintainable approach is to use role-based authorization. The good news is that the tools at our disposal for applying authorization rules work equally well with roles as they do for user accounts. URL authorization rules can specify roles instead of users. The LoginView control, which renders different output for authenticated and anonymous users, can be configured to display different content based on the logged in user's roles. And the Roles API includes methods for determining the logged in user's roles.

This tutorial starts with a look at how the Roles framework associates a user's roles with his security context. It then examines how to apply role-based URL authorization rules. Following that, we will look at using declarative and programmatic means for altering the data displayed and the functionality offered by an ASP.NET page. Let's get started!

Understanding How Roles are Associated with a User's Security Context

Whenever a request enters the ASP.NET pipeline it is associated with a security context, which includes information identifying the requestor. When using forms authentication, an authentication ticket is used as an identity token. As we discussed in the *An Overview of Forms Authentication* and *Forms Authentication Configuration and Advanced Topics* tutorials, the `FormsAuthenticationModule` is responsible for determining the identity of the requestor, which it does during the `AuthenticateRequest` event.

If a valid, non-expired authentication ticket is found, the `FormsAuthenticationModule` decodes it to ascertain the requestor's identity. It creates a new `GenericPrincipal` object and assigns this to the `HttpContext.User` object. The purpose of a principal, like `GenericPrincipal`, is to identify the authenticated user's name and what roles she belong to. This purpose is evident by the fact that all principal objects have an `Identity` property and an `IsInRole(roleName)` method. The `FormsAuthenticationModule`, however, is not interested in recording role

information and the `GenericPrincipal` object it creates does not specify any roles.

If the Roles framework is enabled, the `RoleManagerModule` HTTP Module steps in after the `FormsAuthenticationModule` and identifies the authenticated user's roles during the `PostAuthenticateRequest` event, which fires after the `AuthenticateRequest` event. If the request is from an authenticated user, the `RoleManagerModule` overwrites the `GenericPrincipal` object created by the `FormsAuthenticationModule` and replaces it with a `RolePrincipal` object. The `RolePrincipal` class uses the Roles API to determine what roles the user belongs to.

Figure 1 depicts the ASP.NET pipeline workflow when using forms authentication and the Roles framework. The `FormsAuthenticationModule` executes first, identifies the user via her authentication ticket, and creates a new `GenericPrincipal` object. Next, the `RoleManagerModule` steps in and overwrites the `GenericPrincipal` object with a `RolePrincipal` object.

If an anonymous user visits the site, neither the `FormsAuthenticationModule` nor the `RoleManagerModule` creates a principal object.

Figure 1: The ASP.NET Pipeline Events for an Authenticated User When Using Forms Authentication and the Roles Framework (Click to view full-size image)

Caching Role Information in a Cookie

The `RolePrincipal` object's `IsInRole(roleName)` method calls `Roles.GetRolesForUser` to get the roles for the user in order to determine whether the user is a member of *roleName*. When using the `SqlRoleProvider`, this results in a query to the role store database. When using role-based URL authorization rules the `RolePrincipal`'s `IsInRole` method will be called on every request to a page that is protected by the role-based URL authorization rules. Rather than have to lookup the role information in the database on every request, the Roles framework includes an option to cache the user's roles in a cookie.

If the Roles framework is configured to cache the user's roles in a cookie, the `RoleManagerModule` creates the cookie during the ASP.NET pipeline's `EndRequest` event. This cookie is used in subsequent requests in the `PostAuthenticateRequest`, which is when the `RolePrincipal` object is created. If the cookie is valid and has not expired, the data in the cookie is parsed and used to populate the user's roles, thereby saving the `RolePrincipal` from having to make a call to the `Roles` class to determine the user's roles. Figure 2 depicts this workflow.

Figure 2: The User's Role Information Can Be Stored in a Cookie to Improve Performance (Click to view full-size image)

By default, the role cache cookie mechanism is disabled. It can be enabled through the `<roleManager>` configuration markup in `Web.config`. We discussed using the `<roleManager>` element to specify Role providers in the *Creating and Managing Roles* tutorial, so you should already have this element in your application's `Web.config` file. The role cache cookie settings are specified as attributes of the `<roleManager>` element, and are summarized in Table 1.

> **NOTE**
>
> The configuration settings listed in Table 1 specify the properties of the resulting role cache cookie. For more information on cookies, how they work, and their various properties, read this Cookies tutorial.

PROPERTY	DESCRIPTION
`cacheRolesInCookie`	A Boolean value that indicates whether cookie caching is used. Defaults to `false`.
`cookieName`	The name of the role cache cookie. The default value is ".ASPXROLES".
`cookiePath`	The path for the roles name cookie. The path attribute enables a developer to limit the scope of a cookie to a particular directory hierarchy. The default value is "/", which informs the browser to send the authentication ticket cookie to any request made to the domain.
`cookieProtection`	Indicates what techniques are used to protect the role cache cookie. The allowable values are: `All` (the default); `Encryption`; `None`; and `Validation`. Refer back to Step 3 of the *Forms Authentication Configuration and Advanced Topics* tutorial for more information on these protection levels.
`cookieRequireSSL`	A Boolean value that indicates whether an SSL connection is required to transmit the authentication cookie. The default value is `false`.

PROPERTY	DESCRIPTION
`cookieSlidingExpiration`	A Boolean value that indicates whether the cookie's timeout is reset each time the user visits the site during a single session. The default value is `false`. This value is only pertinent when `createPersistentCookie` is set to `true`.
`cookieTimeout`	Specifies the time, in minutes, after which the authentication ticket cookie expires. The default value is `30`. This value is only pertinent when `createPersistentCookie` is set to `true`.
`createPersistentCookie`	A Boolean value that specifies whether the role cache cookie is a session cookie or persistent cookie. If `false` (the default), a session cookie is used, which is deleted when the browser is closed. If `true`, a persistent cookie is used; it expires `cookieTimeout` number of minutes after it has been created or after the previous visit, depending on the value of `cookieSlidingExpiration`.
`domain`	Specifies the cookie's domain value. The default value is an empty string, which causes the browser to use the domain from which it was issued (such as www.yourdomain.com). In this case, the cookie will **not** be sent when making requests to subdomains, such as admin.yourdomain.com. If you want the cookie to be passed to all subdomains you need to customize the `domain` attribute, setting it to "yourdomain.com".
`maxCachedResults`	Specifies the maximum number of role names that are cached in the cookie. The default is 25. The `RoleManagerModule` does not create a cookie for users that belong to more than `maxCachedResults` roles. Consequently, the `RolePrincipal` object's `IsInRole` method will use the `Roles` class to determine the user's roles. The reason `maxCachedResults` exists is because many user agents do not permit cookies larger than 4,096 bytes. So this cap is meant to reduce the likelihood of exceeding this size limitation. If you have extremely long role names, you may want to consider specifying a smaller `maxCachedResults` value; contrariwise, if you have extremely short role names, you can probably increase this value.

Table 1: The Role Cache Cookie Configuration Options

Let's configure our application to use non-persistent role cache cookies. To accomplish this, update the `<roleManager>` element in `Web.config` to include the following cookie-related attributes:

```
<roleManager enabled="true"
          defaultProvider="SecurityTutorialsSqlRoleProvider"
          cacheRolesInCookie="true"
          createPersistentCookie="false"
          cookieProtection="All">

     <providers>
     ...
     </providers>
</roleManager>
```

I updated the `<roleManager>` element by adding three attributes: `cacheRolesInCookie`, `createPersistentCookie`, and `cookieProtection`. By setting `cacheRolesInCookie` to `true`, the `RoleManagerModule` will now automatically cache the user's roles in a cookie rather than having to lookup the user's role information on each request. I explicitly set the `createPersistentCookie` and `cookieProtection` attributes to `false` and `All`, respectively. Technically, I didn't need to specify values for these attributes since I just assigned them to their default values, but I put them here to make it explicitly clear that I am not using persistent cookies and that the cookie is both encrypted and validated.

That's all there is to it! Henceforth, the Roles framework will cache the users' roles in cookies. If the user's browser does not support cookies, or if their cookies are deleted or lost, somehow, it's no big deal – the `RolePrincipal` object will simply use the `Roles` class in the case that no cookie (or an invalid or expired one) is available.

> **NOTE**
>
> Microsoft's Patterns & Practices group discourages using persistent role cache cookies. Since possession of the role cache cookie is sufficient to prove role membership, if a hacker can somehow gain access to a valid user's cookie he can impersonate that user. The likelihood of this happening increases if the cookie is persisted on the user's browser. For more information on this security recommendation, as well as other security concerns, refer to the Security Question List for ASP.NET 2.0.

Step 1: Defining Role-Based URL Authorization Rules

As discussed in the *User-Based Authorization* tutorial, URL authorization offers a means to restrict access to a set of pages on a user-by-user or role-by-role basis. The URL authorization rules are spelled out in `Web.config` using the `<authorization>` element with `<allow>` and `<deny>` child elements. In addition to the user-related authorization rules discussed in previous tutorials, each `<allow>` and `<deny>` child element can also include:

- A particular role
- A comma-delimited list of roles

For example, the URL authorization rules grant access to those users in the Administrators and Supervisors roles, but deny access to all others:

```
<authorization>
    <allow roles="Administrators, Supervisors" />
    <deny users="*" />
</authorization>
```

The `<allow>` element in the above markup states that the Administrators and Supervisors roles are allowed; the `<deny>` element instructs that *all* users are denied.

Let's configure our application so that the `ManageRoles.aspx`, `UsersAndRoles.aspx`, and `CreateUserWizardWithRoles.aspx` pages are only accessible to those users in the Administrators role, while the `RoleBasedAuthorization.aspx` page remains accessible to all visitors.

To accomplish this, start by adding a `Web.config` file to the `Roles` folder.

Figure 3: Add a `Web.config` File to the `Roles` directory (Click to view full-size image)

Next, add the following configuration markup to `Web.config`:

```
<?xml version="1.0"?>

<configuration>
     <system.web>
          <authorization>
               <allow roles="Administrators" />
               <deny users="*"/>
          </authorization>

     </system.web>

     <!-- Allow all users to visit RoleBasedAuthorization.aspx -->
     <location path="RoleBasedAuthorization.aspx">
          <system.web>
               <authorization>
                    <allow users="*" />

               </authorization>
          </system.web>
     </location>
</configuration>
```

The `<authorization>` element in the `<system.web>` section indicates that only users in the Administrators role may access the ASP.NET resources in the `Roles` directory. The `<location>` element defines an alternate set of URL authorization rules for the `RoleBasedAuthorization.aspx` page, allowing all users to visit the page.

After saving your changes to `Web.config`, log in as a user that is not in the Administrators role and then try to visit one of the protected pages. The `UrlAuthorizationModule` will detect that you do not have permission to visit the requested resource; consequently, the `FormsAuthenticationModule` will redirect you to the login page. The login page will then redirect you to the `UnauthorizedAccess.aspx` page (see Figure 4). This final redirect from the login page to `UnauthorizedAccess.aspx` occurs because of code we added to the login page in Step 2 of the *User-Based Authorization* tutorial. In particular, the login page automatically redirects any authenticated user to `UnauthorizedAccess.aspx` if the querystring contains a `ReturnUrl` parameter, as this parameter indicates that the user arrived at the login page after attempting to view a page he was not authorized to view.

Figure 4: Only Users in the Administrators Role Can View the Protected Pages (Click to view full-size image)

Log off and then log in as a user that is in the Administrators role. Now you should be able to view the three protected pages.

Figure 5: Tito Can Visit the `UsersAndRoles.aspx` Page Because He is in the Administrators Role (Click to view full-size image)

NOTE

When specifying URL authorization rules – for roles or users – it is important to keep in mind that the rules are analyzed one at a time, from the top down. As soon as a match is found, the user is granted or denied access, depending on if the match was found in an `<allow>` or `<deny>` element. **If no match is found, the user is granted access.** Consequently, if you want to restrict access to one or more user accounts, it is imperative that you use a `<deny>` element as the last element in the URL authorization configuration. **If your URL authorization rules do not include a `<deny>` element, all users will be granted access.** For a more thorough discussion on how the URL authorization rules are analyzed, refer back to the "A Look at How the `UrlAuthorizationModule` Uses the Authorization Rules to Grant or Deny Access" section of the *User-Based Authorization* tutorial.

Step 2: Limiting Functionality Based On the Currently Logged In User's Roles

URL authorization makes it easy to specify coarse authorization rules that state what identities are permitted and which ones are denied from viewing a particular page (or all pages in a folder and its subfolders). However, in certain cases we may want to allow all users to visit a page, but limit the page's functionality based on the visiting user's roles. This may entail showing or hiding data based on the user's role, or offering additional functionality to users that belong to a particular role.

Such fine grain role-based authorization rules can be implemented either declaratively or programmatically (or through some combination of the two). In the next section we will see how to implement declarative fine grain authorization via the LoginView control. Following that, we will explore programmatic techniques. Before we can look at applying fine grain authorization rules, however, we first need to create a page whose functionality depends on the role of the user visiting it.

Let's create a page that lists all of the user accounts in the system in a GridView. The GridView will include each user's username, email address, last login date, and comments about the user. In addition to displaying each user's information, the GridView will include edit and delete capabilities. We will initially create this page with the edit and delete functionality available to all users. In the "Using the LoginView Control" and "Programmatically Limiting Functionality" sections we will see how to enable or disable these features based on the visiting user's role.

NOTE

The ASP.NET page we are about to build uses a GridView control to display the user accounts. Since this tutorial series focuses on forms authentication, authorization, user accounts, and roles, I do not want to spend too much time discussing the inner workings of the GridView control. While this tutorial provides specific step-by-step instructions for setting up this page, it does not delve into the details of why certain choices were made, or what effect particular properties have on the rendered output. For a thorough examination of the GridView control, check out my *Working with Data in ASP.NET 2.0* tutorial series.

Start by opening the `RoleBasedAuthorization.aspx` page in the `Roles` folder. Drag a GridView from the page onto the Designer and set its `ID` to `UserGrid`. In a moment we will write code that calls the `Membership.GetAllUsers` method and binds the resulting `MembershipUserCollection` object to the GridView. The `MembershipUserCollection` contains a `MembershipUser` object for each user account in the system; `MembershipUser` objects have properties like `UserName`, `Email`, `LastLoginDate`, and so forth.

Before we write the code that binds the user accounts to the grid, let's first define the GridView's fields. From the GridView's Smart Tag, click the "Edit Columns" link to launch the Fields dialog box (see Figure 6). From here, uncheck the "Auto-generate fields" checkbox in the lower left corner. Since we want this GridView to include editing and deleting capabilities, add a CommandField and set its `ShowEditButton` and `ShowDeleteButton`

properties to True. Next, add four fields for displaying the `UserName`, `Email`, `LastLoginDate`, and `Comment` properties. Use a BoundField for the two read-only properties (`UserName` and `LastLoginDate`) and TemplateFields for the two editable fields (`Email` and `Comment`).

Have the first BoundField display the `UserName` property; set its `HeaderText` and `DataField` properties to "UserName". This field will not be editable, so set its `ReadOnly` property to True. Configure the `LastLoginDate` BoundField by setting its `HeaderText` to "Last Login" and its `DataField` to "LastLoginDate". Let's format the output of this BoundField so that just the date is displayed (instead of the date and time). To accomplish this, set this BoundField's `HtmlEncode` property to False and its `DataFormatString` property to "{0:d}". Also set the `ReadOnly` property to True.

Set the `HeaderText` properties of the two TemplateFields to "Email" and "Comment".

Figure 6: The GridView's Fields Can Be Configured Through the Fields Dialog Box (Click to view full-size image)

We now need to define the `ItemTemplate` and `EditItemTemplate` for the "Email" and "Comment" TemplateFields. Add a Label Web control to each of the `ItemTemplate` s and bind their `Text` properties to the `Email` and `Comment` properties, respectively.

For the "Email" TemplateField, add a TextBox named `Email` to its `EditItemTemplate` and bind its `Text` property to the `Email` property using two-way databinding. Add a RequiredFieldValidator and RegularExpressionValidator to the `EditItemTemplate` to ensure that a visitor editing the Email property has entered a valid email address. For the "Comment" TemplateField, add a multi-line TextBox named `Comment` to its `EditItemTemplate`. Set the TextBox's `Columns` and `Rows` properties to 40 and 4, respectively, and then bind its `Text` property to the `Comment` property using two-way databinding.

After configuring these TemplateFields, their declarative markup should look similar to the following:

```
<asp:TemplateField HeaderText="Email">
     <ItemTemplate>
          <asp:Label runat="server" ID="Label1" Text='<%# Eval("Email") %>'></asp:Label>

     </ItemTemplate>
     <EditItemTemplate>
          <asp:TextBox runat="server" ID="Email" Text='<%# Bind("Email") %>'></asp:TextBox>

          <asp:RequiredFieldValidator ID="RequiredFieldValidator1" runat="server"
               ControlToValidate="Email" Display="Dynamic"
               ErrorMessage="You must provide an email address."
               SetFocusOnError="True">*</asp:RequiredFieldValidator>

          <asp:RegularExpressionValidator ID="RegularExpressionValidator1" runat="server"
               ControlToValidate="Email" Display="Dynamic"
               ErrorMessage="The email address you have entered is not valid. Please fix
               this and try again."
               SetFocusOnError="True"

               ValidationExpression="\w+([-+.']\w+)*@\w+([-.]\w+)*\.\w+([-.]\w+)*">*
          </asp:RegularExpressionValidator>
     </EditItemTemplate>
</asp:TemplateField>

<asp:TemplateField HeaderText="Comment">
     <ItemTemplate>
          <asp:Label runat="server" ID="Label2" Text='<%# Eval("Comment") %>'></asp:Label>

     </ItemTemplate>
     <EditItemTemplate>
          <asp:TextBox runat="server" ID="Comment" TextMode="MultiLine"
               Columns="40" Rows="4" Text='<%# Bind("Comment") %>'>

          </asp:TextBox>
     </EditItemTemplate>
</asp:TemplateField>
```

When editing or deleting a user account we will need to know that user's `UserName` property value. Set the GridView's `DataKeyNames` property to "UserName" so that this information is available through the GridView's `DataKeys` collection.

Finally, add a ValidationSummary control to the page and set its `ShowMessageBox` property to True and its `ShowSummary` property to False. With these settings, the ValidationSummary will display a client-side alert if the user attempts to edit a user account with a missing or invalid email address.

```
<asp:ValidationSummary ID="ValidationSummary1"
               runat="server"
               ShowMessageBox="True"
               ShowSummary="False" />
```

We have now completed this page's declarative markup. Our next task is to bind the set of user accounts to the GridView. Add a method named `BindUserGrid` to the `RoleBasedAuthorization.aspx` page's code-behind class that binds the `MembershipUserCollection` returned by `Membership.GetAllUsers` to the `UserGrid` GridView. Call this method from the `Page_Load` event handler on the first page visit.

```
protected void Page_Load(object sender, EventArgs e)
{
     if (!Page.IsPostBack)
          BindUserGrid();
}

private void BindUserGrid()
{
     MembershipUserCollection allUsers = Membership.GetAllUsers();
     UserGrid.DataSource = allUsers;
     UserGrid.DataBind();
}
```

With this code in place, visit the page through a browser. As Figure 7 shows, you should see a GridView listing information about each user account in the system.

Figure 7: The `UserGrid` GridView Lists Information About Each User in the System (Click to view full-size image)

> **NOTE**
>
> The `UserGrid` GridView lists all of the users in a non-paged interface. This simple grid interface is not suitable for scenarios where there are several dozen or more users. One option is to configure the GridView to enable paging. The `Membership.GetAllUsers` method has two overloads: one that accepts no input parameters and returns all of the users and one that takes in integer values for the page index and page size, and returns only the specified subset of the users. The second overload can be used to more efficiently page through the users since it returns just the precise subset of user accounts rather than *all* of them. If you have thousands of user accounts, you might want to consider a filter-based interface, one that only shows those users whose UserName begins with a selected character, for instance. The `Membership.FindUsersByName method` is ideal for building a filter-based user interface. We will look at building such an interface in a future tutorial.

The GridView control offers built-in editing and deleting support when the control is bound to a properly configured data source control, such as the SqlDataSource or ObjectDataSource. The `UserGrid` GridView, however, has its data programmatically bound; therefore, we must write code to perform these two tasks. In particular, we will need to create event handlers for the GridView's `RowEditing`, `RowCancelingEdit`, `RowUpdating`, and `RowDeleting` events, which are fired when a visitor clicks the GridView's Edit, Cancel, Update, or Delete buttons.

Start by creating the event handlers for the GridView's `RowEditing`, `RowCancelingEdit`, and `RowUpdating` events and then add the following code:

```
protected void UserGrid_RowEditing(object sender, GridViewEditEventArgs e)
{
     // Set the grid's EditIndex and rebind the data

     UserGrid.EditIndex = e.NewEditIndex;
     BindUserGrid();
}

protected void UserGrid_RowCancelingEdit(object sender, GridViewCancelEditEventArgs e)
{
     // Revert the grid's EditIndex to -1 and rebind the data
     UserGrid.EditIndex = -1;
     BindUserGrid();
}

protected void UserGrid_RowUpdating(object sender, GridViewUpdateEventArgs e)
{
     // Exit if the page is not valid
     if (!Page.IsValid)
          return;

     // Determine the username of the user we are editing
     string UserName = UserGrid.DataKeys[e.RowIndex].Value.ToString();

     // Read in the entered information and update the user
     TextBox EmailTextBox = UserGrid.Rows[e.RowIndex].FindControl("Email") as TextBox;
     TextBox CommentTextBox = UserGrid.Rows[e.RowIndex].FindControl("Comment") as TextBox;

     // Return information about the user
     MembershipUser UserInfo = Membership.GetUser(UserName);

     // Update the User account information
     UserInfo.Email = EmailTextBox.Text.Trim();
     UserInfo.Comment = CommentTextBox.Text.Trim();

     Membership.UpdateUser(UserInfo);

     // Revert the grid's EditIndex to -1 and rebind the data
     UserGrid.EditIndex = -1;
     BindUserGrid();
}
```

The `RowEditing` and `RowCancelingEdit` event handlers simply set the GridView's `EditIndex` property and then rebind the list of user accounts to the grid. The interesting stuff happens in the `RowUpdating` event handler. This event handler starts by ensuring that the data is valid and then grabs the `UserName` value of the edited user account from the `DataKeys` collection. The `Email` and `Comment` TextBoxes in the two TemplateFields' `EditItemTemplate` s are then programmatically referenced. Their `Text` properties contain the edited email address and comment.

In order to update a user account through the Membership API we need to first get the user's information, which we do via a call to `Membership.GetUser(userName)`. The returned `MembershipUser` object's `Email` and `Comment` properties are then updated with the values entered into the two TextBoxes from the editing interface. Finally, these modifications are saved with a call to `Membership.UpdateUser`. The `RowUpdating` event handler completes by reverting the GridView to its pre-editing interface.

Next, create the `RowDeleting` event handler and then add the following code:

```
protected void UserGrid_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
     // Determine the username of the user we are editing
     string UserName = UserGrid.DataKeys[e.RowIndex].Value.ToString();

     // Delete the user
     Membership.DeleteUser(UserName);

     // Revert the grid's EditIndex to -1 and rebind the data
     UserGrid.EditIndex = -1;
     BindUserGrid();
}
```

The above event handler starts by grabbing the `UserName` value from the GridView's `DataKeys` collection; this `UserName` value is then passed into the Membership class's `DeleteUser` method. The `DeleteUser` method deletes the user account from the system, including related membership data (such as what roles this user belongs to). After deleting the user, the grid's `EditIndex` is set to -1 (in case the user clicked Delete while another row was in edit mode) and the `BindUserGrid` method is called.

> **NOTE**
> The Delete button does not require any sort of confirmation from the user before deleting the user account. I encourage you to add some form of user confirmation to lessen the chance of an account being accidentally deleted. One of the easiest ways to confirm an action is through a client-side confirm dialog box. For more information on this technique, see Adding Client-Side Confirmation When Deleting.

Verify that this page functions as expected. You should be able to edit any user's email address and comment, as well as delete any user account. Since the `RoleBasedAuthorization.aspx` page is accessible to all users, any user – even anonymous visitors – can visit this page and edit and delete user accounts! Let's update this page so that only users in the Supervisors and Administrators roles can edit a user's email address and comment, and only Administrators can delete a user account.

The "Using the LoginView Control" section looks at using the LoginView control to show instructions specific to the user's role. If a person in the Administrators role visits this page, we will show instructions on how to edit and delete users. If a user in the Supervisors role reaches this page, we will show instructions on editing users. And if the visitor is anonymous or is not in either the Supervisors or Administrators role, we will display a message explaining that they cannot edit or delete user account information. In the "Programmatically Limiting Functionality" section we will write code that programmatically shows or hides the Edit and Delete buttons based on the user's role.

Using the LoginView Control

As we've seen in past tutorials, the LoginView control is useful for displaying different interfaces for authenticated and anonymous users, but the LoginView control can also be used to display different markup based on the user's roles. Let's use a LoginView control to display different instructions based on the visiting user's role.

Start by adding a LoginView above the `UserGrid` GridView. As we've discussed earlier, the LoginView control has two built-in templates: `AnonymousTemplate` and `LoggedInTemplate`. Enter a brief message in both of these templates that informs the user that they cannot edit or delete any user information.

```
<asp:LoginView ID="LoginView1" runat="server">
     <LoggedInTemplate>
          You are not a member of the Supervisors or Administrators roles. Therefore you
          cannot edit or delete any user information.
     </LoggedInTemplate>
     <AnonymousTemplate>
          You are not logged into the system. Therefore you cannot edit or delete any user

          information.
     </AnonymousTemplate>
</asp:LoginView>
```

In addition to the `AnonymousTemplate` and `LoggedInTemplate`, the LoginView control can include *RoleGroups*, which are role-specific templates. Each RoleGroup contains a single property, `Roles`, which specifies what roles the RoleGroup applies to. The `Roles` property can be set to a single role (like "Administrators") or to a comma-delimited list of roles (like "Administrators, Supervisors").

To manage the RoleGroups, click the "Edit RoleGroups" link from the control's Smart Tag to bring up the RoleGroup Collection Editor. Add two new RoleGroups. Set the first RoleGroup's `Roles` property to "Administrators" and the second's to "Supervisors".

Figure 8: Manage the LoginView's Role-Specific Templates Through the RoleGroup Collection Editor (Click to view full-size image)

Click OK to close the RoleGroup Collection Editor; this updates the LoginView's declarative markup to include a `<RoleGroups>` section with an `<asp:RoleGroup>` child element for each RoleGroup defined in the RoleGroup Collection Editor. Furthermore, the "Views" drop-down list in the LoginView's Smart Tag - which initially listed just the `AnonymousTemplate` and `LoggedInTemplate` – now includes the added RoleGroups as well.

Edit the RoleGroups so that users in the Supervisors role are displayed instructions on how to edit user accounts, while users in the Administrators role are shown instructions for editing and deleting. After making these changes, your LoginView's declarative markup should look similar to the following.

```
<asp:LoginView ID="LoginView1" runat="server">
     <RoleGroups>
          <asp:RoleGroup Roles="Administrators">
               <ContentTemplate>
                    As an Administrator, you may edit and delete user accounts.
                    Remember: With great power comes great responsibility!

               </ContentTemplate>
          </asp:RoleGroup>
          <asp:RoleGroup Roles="Supervisors">
               <ContentTemplate>
                    As a Supervisor, you may edit users&#39; Email and Comment information.
                    Simply click the Edit button, make your changes, and then click Update.
               </ContentTemplate>
          </asp:RoleGroup>
     </RoleGroups>

     <LoggedInTemplate>
          You are not a member of the Supervisors or Administrators roles.
          Therefore you cannot edit or delete any user information.
     </LoggedInTemplate>
     <AnonymousTemplate>
          You are not logged into the system. Therefore you cannot edit or delete any user
          information.
     </AnonymousTemplate>
</asp:LoginView>
```

After making these changes, save the page and then visit it through a browser. First visit the page as an anonymous user. You should be shown the message, "You are not logged into the system. Therefore you cannot edit or delete any user information." Then log in as an authenticated user, but one that is neither in the Supervisors nor Administrators role. This time you should see the message, "You are not a member of the Supervisors or Administrators roles. Therefore you cannot edit or delete any user information."

Next, log in as a user who is a member of the Supervisors role. This time you should see the Supervisors role-specific message (see Figure 9). And if you log in as a user in the Administrators role you should see the Administrators role-specific message (see Figure 10).

Figure 9: Bruce is Shown the Supervisors Role-Specific Message (Click to view full-size image)

Figure 10: Tito is Shown the Administrators Role-Specific Message (Click to view full-size image)

As the screen shots in Figures 9 and 10 show, the LoginView only renders one template, even if multiple templates apply. Bruce and Tito are both logged in users, yet the LoginView renders only the matching RoleGroup and not the `LoggedInTemplate`. Moreover, Tito belongs to both the Administrators and Supervisors roles, yet the LoginView control renders the Administrators role-specific template instead of the Supervisors one.

Figure 11 illustrates the workflow used by the LoginView control to determine what template to render. Note that if there is more than one RoleGroup specified, the LoginView template renders the *first* RoleGroup that matches. In other words, if we had placed the Supervisors RoleGroup as the first RoleGroup and the Administrators as the second, then when Tito visited this page he would see the Supervisors message.

Figure 11: The LoginView Control's Workflow for Determining What Template to Render (Click to view full-size image)

Programmatically Limiting Functionality

While the LoginView control displays different instructions based on the role of the user visiting the page, the Edit and Cancel buttons remain visible to all. We need to programmatically hide the Edit and Delete buttons for

anonymous visitors and users who are in neither the Supervisors nor Administrators role. We need to hide the Delete button for everyone who is not an Administrator. In order to accomplish this we will write a bit of code that programmatically references the CommandField's Edit and Delete LinkButtons and sets their `Visible` properties to `false`, if necessary.

The easiest way to programmatically reference controls in a CommandField is to first convert it to a template. To accomplish this, click the "Edit Columns" link from the GridView's Smart Tag, select the CommandField from the list of current fields, and click the "Convert this field into a TemplateField" link. This turns the CommandField into a TemplateField with an `ItemTemplate` and `EditItemTemplate`. The `ItemTemplate` contains the Edit and Delete LinkButtons while the `EditItemTemplate` houses the Update and Cancel LinkButtons.

Figure 12: Convert the CommandField Into a TemplateField (Click to view full-size image)

Update the Edit and Delete LinkButtons in the `ItemTemplate`, setting their `ID` properties to values of `EditButton` and `DeleteButton`, respectively.

```
<asp:TemplateField ShowHeader="False">
     <EditItemTemplate>
          <asp:LinkButton ID="LinkButton1" runat="server" CausesValidation="True"
               CommandName="Update" Text="Update"></asp:LinkButton>

           <asp:LinkButton ID="LinkButton2" runat="server" CausesValidation="False"
                CommandName="Cancel" Text="Cancel"></asp:LinkButton>

     </EditItemTemplate>
     <ItemTemplate>
          <asp:LinkButton ID="EditButton" runat="server" CausesValidation="False"
               CommandName="Edit" Text="Edit"></asp:LinkButton>

           <asp:LinkButton ID="DeleteButton" runat="server" CausesValidation="False"
               CommandName="Delete" Text="Delete"></asp:LinkButton>

     </ItemTemplate>
</asp:TemplateField>
```

Whenever data is bound to the GridView, the GridView enumerates the records in its `DataSource` property and generates a corresponding `GridViewRow` object. As each `GridViewRow` object is created, the `RowCreated` event is fired. In order to hide the Edit and Delete buttons for unauthorized users, we need to create an event handler for this event and programmatically reference the Edit and Delete LinkButtons, setting their `Visible` properties

accordingly.

Create an event handler the `RowCreated` event and then add the following code:

```
protected void UserGrid_RowCreated(object sender, GridViewRowEventArgs e)
{
     if (e.Row.RowType == DataControlRowType.DataRow && e.Row.RowIndex != UserGrid.EditIndex)
     {
          // Programmatically reference the Edit and Delete LinkButtons
          LinkButton EditButton = e.Row.FindControl("EditButton") as LinkButton;

          LinkButton DeleteButton = e.Row.FindControl("DeleteButton") as LinkButton;

          EditButton.Visible = (User.IsInRole("Administrators") || User.IsInRole("Supervisors"));
          DeleteButton.Visible = User.IsInRole("Administrators");
     }
}
```

Keep in mind that the `RowCreated` event fires for *all* of the GridView rows, including the header, the footer, the pager interface, and so forth. We only want to programmatically reference the Edit and Delete LinkButtons if we are dealing with a data row not in edit mode (since the row in edit mode has Update and Cancel buttons instead of Edit and Delete). This check is handled by the `if` statement.

If we are dealing with a data row that is not in edit mode, the Edit and Delete LinkButtons are referenced and their `Visible` properties are set based on the Boolean values returned by the `User` object's `IsInRole(roleName)` method. The User object references the principal created by the `RoleManagerModule`; consequently, the `IsInRole(roleName)` method uses the Roles API to determine whether the current visitor belongs to *roleName*.

> **NOTE**
> We could have used the Roles class directly, replacing the call to `User.IsInRole(roleName)` with a call to the `Roles.IsUserInRole(roleName)` method. I decided to use the principal object's `IsInRole(roleName)` method in this example because it is more efficient than using the Roles API directly. Earlier in this tutorial we configured the role manager to cache the user's roles in a cookie. This cached cookie data is only utilized when the principal's `IsInRole(roleName)` method is called; direct calls to the Roles API always involve a trip to the role store. Even if roles are not cached in a cookie, calling the principal object's `IsInRole(roleName)` method is usually more efficient because when it is called for the first time during a request it caches the results. The Roles API, on the other hand, does not perform any caching. Because the `RowCreated` event is fired once for every row in the GridView, using `User.IsInRole(roleName)` involves just one trip to the role store whereas `Roles.IsUserInRole(roleName)` requires *N* trips, where *N* is the number of user accounts displayed in the grid.

The Edit button's `Visible` property is set to `true` if the user visiting this page is in the Administrators or Supervisors role; otherwise it is set to `false`. The Delete button's `Visible` property is set to `true` only if the user is in the Administrators role.

Test this page through a browser. If you visit the page as an anonymous visitor or as a user that is neither a Supervisor nor an Administrator, the CommandField is empty; it still exists, but as a thin sliver without the Edit or Delete buttons.

> **NOTE**
> It is possible to hide the CommandField altogether when a non-Supervisor and non-Administrator is visiting the page. I leave this as an exercise for the reader.

Figure 13: The Edit and Delete Buttons are Hidden for Non-Supervisors and Non-Administrators (Click to view full-size image)

If a user that belongs to the Supervisors role (but not to the Administrators role) visits, he sees only the Edit button.

Figure 14: While the Edit Button is Available for Supervisors, the Delete Button is Hidden (Click to view full-size image)

And if an Administrator visits, she has access to both the Edit and Delete buttons.

Figure 15: The Edit and Delete Buttons are Available Only for Administrators (Click to view full-size image)

Step 3: Applying Role-Based Authorization Rules to Classes and Methods

In Step 2 we limited edit capabilities to users in the Supervisors and Administrators roles and delete capabilities to Administrators only. This was accomplished by hiding the associated user interface elements for unauthorized users through programmatic techniques. Such measures do not guarantee that an unauthorized user will be unable to perform a privileged action. There may be user interface elements that are added later or that we forgot to hide for unauthorized users. Or a hacker may discover some other way to get the ASP.NET page to execute the desired method.

An easy way to ensure that a particular piece of functionality cannot be accessed by an unauthorized user is to decorate that class or method with the `PrincipalPermission` attribute. When the .NET runtime uses a class or executes one of its methods, it checks to ensure that the current security context has permission. The `PrincipalPermission` attribute provides a mechanism through which we can define these rules.

We looked at using the `PrincipalPermission` attribute back in the *User-Based Authorization* tutorial. Specifically, we saw how to decorate the GridView's `SelectedIndexChanged` and `RowDeleting` event handler so that they could only be executed by authenticated users and Tito, respectively. The `PrincipalPermission` attribute works just as well with roles.

Let's demonstrate using the `PrincipalPermission` attribute on the GridView's `RowUpdating` and `RowDeleting` event handlers to prohibit execution for non-authorized users. All we need to do is add the appropriate attribute atop each function definition:

```
[PrincipalPermission(SecurityAction.Demand, Role = "Administrators")]
[PrincipalPermission(SecurityAction.Demand, Role = "Supervisors")]
protected void UserGrid_RowUpdating(object sender, GridViewUpdateEventArgs e)
{
    ...
}

[PrincipalPermission(SecurityAction.Demand, Role = "Administrators")]
protected void UserGrid_RowDeleting(object sender, GridViewDeleteEventArgs e)
{
    ...
}
```

The attribute for the `RowUpdating` event handler dictates that only users in the Administrators or Supervisors

roles can execute the event handler, where as the attribute on the `RowDeleting` event handler limits the execution to users in the Administrators role.

> **NOTE**
> The `PrincipalPermission` attribute is represented as a class in the `System.Security.Permissions` namespace. Be sure to add a `using System.Security.Permissions` statement at the top of your code-behind class file to import this namespace.

If, somehow, a non-Administrator attempts to execute the `RowDeleting` event handler or if a non-Supervisor or non-Administrator attempts to execute the `RowUpdating` event handler, the .NET runtime will raise a `SecurityException`.

Figure 16: If the Security Context is not Authorized to Execute the Method, a `SecurityException` is Thrown (Click to view full-size image)

In addition to ASP.NET pages, many applications also have an architecture that includes various layers, such as Business Logic and Data Access Layers. These layers are typically implemented as Class Libraries and offer classes and methods for performing business logic- and data-related functionality. The `PrincipalPermission` attribute is useful for applying authorization rules to these layers as well.

For more information on using the `PrincipalPermission` attribute to define authorization rules on classes and methods, refer to Scott Guthrie's blog entry Adding Authorization Rules to Business and Data Layers Using `PrincipalPermissionAttributes`.

Summary

In this tutorial we looked at how to specify coarse and fine grain authorization rules based on the user's roles. ASP.NET's URL authorization feature allows a page developer to specify what identities are allowed or denied access to what pages. As we saw back in the *User-Based Authorization* tutorial, URL authorization rules can be applied on a user-by-user basis. They can also be applied on a role-by-role basis, as we saw in Step 1 of this tutorial.

Fine grain authorization rules may be applied declaratively or programmatically. In Step 2 we looked at using the LoginView control's RoleGroups feature to render different output based on the visiting user's roles. We also looked at ways to programmatically determine if a user belongs to a specific role and how to adjust the page's functionality accordingly.

Happy Programming!

Creating and Managing Roles (VB)

2/20/2020 • 20 minutes to read • Edit Online

Download Code or Download PDF

This tutorial examines the steps necessary for configuring the Roles framework. Following that, we will build web pages to create and delete roles.

Introduction

In the *User-Based Authorization* tutorial we looked at using URL authorization to restrict certain users from a set of pages and explored declarative and programmatic techniques for adjusting an ASP.NET page's functionality based on the visiting user. Granting permission for page access or functionality on a user-by-user basis, however, can become a maintenance nightmare in scenarios where there are many user accounts or when users' privileges change often. Any time a user gains or loses authorization to perform a particular task, the administrator needs to update the appropriate URL authorization rules, declarative markup, and code.

It usually helps to classify users into groups or *roles* and then to apply permissions on a role-by-role basis. For example, most web applications have a certain set of pages or tasks that are reserved only for administrative users. Using the techniques learned in the *User-Based Authorization* tutorial, we would add the appropriate URL authorization rules, declarative markup, and code to allow the specified user accounts to perform administrative tasks. But if a new administrator was added or if an existing administrator needed to have her administration rights revoked, we would have to return and update the configuration files and web pages. With roles, however, we could create a role called Administrators and assign those trusted users to the Administrators role. Next, we would add the appropriate URL authorization rules, declarative markup, and code to allow the Administrators role to perform the various administrative tasks. With this infrastructure in place, adding new administrators to the site or removing existing ones is as simple as including or removing the user from the Administrators role. No configuration, declarative markup, or code changes are necessary.

ASP.NET offers a Roles framework for defining roles and associating them with user accounts. With the Roles framework we can create and delete roles, add users to or remove users from a role, determine the set of users that belong to a particular role, and tell whether a user belongs to a particular role. Once the Roles framework has been configured, we can limit access to pages on a role-by-role basis through URL authorization rules and show or hide additional information or functionality on a page based on the currently logged on user's roles.

This tutorial examines the steps necessary for configuring the Roles framework. Following that, we will build web pages to create and delete roles. In the *Assigning Roles to Users* tutorial we will look at how to add and remove users from roles. And in the *Role-Based Authorization* tutorial we will see how to limit access to pages on a role-by-role basis along with how to adjust page functionality depending on the visiting user's role. Let's get started!

Step 1: Adding New ASP.NET Pages

In this tutorial and the next two we will be examining various roles-related functions and capabilities. We will need a series of ASP.NET pages to implement the topics examined throughout these tutorials. Let's create these pages and update the site map.

Start by creating a new folder in the project named `Roles`. Next, add four new ASP.NET pages to the `Roles` folder, linking each page with the `Site.master` master page. Name the pages:

- `ManageRoles.aspx`
- `UsersAndRoles.aspx`
- `CreateUserWizardWithRoles.aspx`
- `RoleBasedAuthorization.aspx`

At this point your project's Solution Explorer should look similar to the screen shot shown in Figure 1.

Figure 1: Four New Pages Have Been Added to the `Roles` Folder (Click to view full-size image)

Each page should, at this point, have the two Content controls, one for each of the master page's ContentPlaceHolders: `MainContent` and `LoginContent`.

```
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="LoginContent" Runat="Server">
</asp:Content>
```

Recall that the `LoginContent` ContentPlaceHolder's default markup displays a link to log on or log off the site, depending on whether the user is authenticated. The presence of the `Content2` Content control in the ASP.NET page, however, overrides the master page's default markup. As we discussed in *An Overview of Forms Authentication* tutorial, overriding the default markup is useful in pages where we do not want to display login-related options in the left column.

For these four pages, however, we want to show the master page's default markup for the `LoginContent` ContentPlaceHolder. Therefore, remove the declarative markup for the `Content2` Content control. After doing so, each of the four page's markup should contain just one Content control.

Finally, let's update the site map (`Web.sitemap`) to include these new web pages. Add the following XML after the `<siteMapNode>` we added for the Membership tutorials.

```
<siteMapNode title="Roles">
 <siteMapNode url="~/Roles/ManageRoles.aspx" title="Manage Roles" />
 <siteMapNode url="~/Roles/UsersAndRoles.aspx" title="Users and Roles" />
 <siteMapNode url="~/Roles/CreateUserWizardWithRoles.aspx" title="Create Account (with Roles)"/>
 <siteMapNode url="~/Roles/RoleBasedAuthorization.aspx" title="Role-Based Authorization" />
</siteMapNode>
```

With the site map updated, visit the site through a browser. As Figure 2 shows, the navigation on the left now includes items for the Roles tutorials.

Figure 2: Four New Pages Have Been Added to the `Roles` Folder (Click to view full-size image)

Step 2: Specifying and Configuring the Roles Framework Provider

Like the Membership framework, the Roles framework is built atop the provider model. As discussed in the *Security Basics and ASP.NET Support* tutorial, the .NET Framework ships with three built-in Roles providers: `AuthorizationStoreRoleProvider`, `WindowsTokenRoleProvider`, and `SqlRoleProvider`. This tutorial series focuses on the `SqlRoleProvider`, which uses a Microsoft SQL Server database as the role store.

Underneath the covers the Roles framework and `SqlRoleProvider` work just like the Membership framework and `SqlMembershipProvider`. The .NET Framework contains a `Roles` class that serves as the API to the Roles framework. The `Roles` class has shared methods like `CreateRole`, `DeleteRole`, `GetAllRoles`, `AddUserToRole`, `IsUserInRole`, and so forth. When one of these methods is invoked, the `Roles` class delegates the call to the configured provider. The `SqlRoleProvider` works with the role-specific tables (`aspnet_Roles` and `aspnet_UsersInRoles`) in response.

In order to use the `SqlRoleProvider` provider in our application, we need to specify what database to use as the store. The `SqlRoleProvider` expects the specified role store to have certain database tables, views, and stored procedures. These requisite database objects can be added using the `aspnet_regsql.exe` tool. At this point we already have a database with the schema necessary for the `SqlRoleProvider`. Back in the *Creating the Membership Schema in SQL Server* tutorial we created a database named `SecurityTutorials.mdf` and used `aspnet_regsql.exe` to add the application services, which included the database objects required by the `SqlRoleProvider`. Therefore we just need to tell the Roles framework to enable role support and to use the `SqlRoleProvider` with the `SecurityTutorials.mdf` database as the role store.

The Roles framework is configured via the `<roleManager>` element in the application's `Web.config` file. By default, role support is disabled. To enable it, you must set the `<roleManager>` element's `enabled` attribute to `true` like so:

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 ... Additional configuration markup removed for brevity ...

 <roleManager enabled="true" />
 <system.web>
</configuration>
```

By default, all web applications have a Roles provider named `AspNetSqlRoleProvider` of type `SqlRoleProvider`. This default provider is registered in `machine.config` (located at `%WINDIR%\Microsoft.Net\Framework\v2.0.50727\CONFIG`):

```
<roleManager>
 <providers>
 <add name="AspNetSqlRoleProvider"
 connectionStringName="LocalSqlServer"
 applicationName="/"
 type="System.Web.Security.SqlRoleProvider,
 System.Web, Version=2.0.0.0, Culture=neutral, PublicKeyToken=b03f5f7f11d50a3a"/>
 </providers>
</roleManager>
```

The provider's `connectionStringName` attribute specifies the role store that is used. The `AspNetSqlRoleProvider` provider sets this attribute to `LocalSqlServer`, which is also defined in `machine.config` and points, by default, to a SQL Server 2005 Express Edition database in the `App_Data` folder named `aspnet.mdf`.

Consequently, if we simply enable the Roles framework without specifying any provider information in our application's `Web.config` file, the application uses the default registered Roles provider, `AspNetSqlRoleProvider`. If the `~/App_Data/aspnet.mdf` database does not exist, the ASP.NET runtime will automatically create it and add the application services schema. However, we don't want to use the `aspnet.mdf` database; rather, we want to use the `SecurityTutorials.mdf` database that we have already created and added the application services schema to. This modification can be accomplished in one of two ways:

- **Specify a value for the `LocalSqlServer` connection string name in `Web.config`.** By overwriting the `LocalSqlServer` connection string name value in `Web.config`, we can use the default registered Roles provider (`AspNetSqlRoleProvider`) and have it correctly work with the `SecurityTutorials.mdf` database. For more information on this technique, see Scott Guthrie's blog post, Configuring ASP.NET 2.0 Application Services to Use SQL Server 2000 or SQL Server 2005.
- **Add a new registered provider of type `SqlRoleProvider` and configure its `connectionStringName` setting to point to the `SecurityTutorials.mdf` database.** This is the approach I recommended and used in the *Creating the Membership Schema in SQL Server* tutorial, and it is the approach I will use in this tutorial as well.

Add the following Roles configuration markup to the `Web.config` file. This markup registers a new provider named `SecurityTutorialsSqlRoleProvider.`

```
<?xml version="1.0"?>
<configuration>
 <connectionStrings>
 <add name="SecurityTutorialsConnectionString"
 connectionString="..."/>
 </connectionStrings>

 <system.web>
 ... Additional configuration markup removed for brevity ...

    <roleManager enabled="true" defaultProvider="SecurityTutorialsSqlRoleProvider">
      <providers>
 <add name="SecurityTutorialsSqlRoleProvider"
 type="System.Web.Security.SqlRoleProvider"
 applicationName="SecurityTutorials"
 connectionStringName="SecurityTutorialsConnectionString"/>
 </providers>
 </roleManager>
 <system.web>
</configuration>
```

The above markup defines the `SecurityTutorialsSqlRoleProvider` as the default provider (via the `defaultProvider` attribute in the `<roleManager>` element). It also sets the `SecurityTutorialsSqlRoleProvider`'s `applicationName` setting to `SecurityTutorials`, which is the same `applicationName` setting used by the Membership provider (`SecurityTutorialsSqlMembershipProvider`). While not shown here, the `<add>` element for the `SqlRoleProvider` may also contain a `commandTimeout` attribute to specify the database timeout duration, in seconds. The default value is 30.

With this configuration markup in place, we are ready to start using role functionality within our application.

> **NOTE**
> The above configuration markup illustrates using the `<roleManager>` element's `enabled` and `defaultProvider` attributes. There are a number of other attributes that affect how the Roles framework associates role information on a user-by-user basis. We will examine these settings in the *Role-Based Authorization* tutorial.

Step 3: Examining the Roles API

The Roles framework's functionality is exposed via the `Roles` class, which contains thirteen shared methods for performing role-based operations. When we look at creating and deleting roles in Steps 4 and 6 we will use the `CreateRole` and `DeleteRole` methods, which add or remove a role from the system.

To get a list of all of the roles in the system, use the `GetAllRoles` method (see Step 5). The `RoleExists` method returns a Boolean value indicating whether a specified role exists.

In the next tutorial we will examine how to associate users with roles. The `Roles` class's `AddUserToRole`, `AddUserToRoles`, `AddUsersToRole`, and `AddUsersToRoles` methods add one or more users to one or more roles. To remove users from roles, use the `RemoveUserFromRole`, `RemoveUserFromRoles`, `RemoveUsersFromRole`, or `RemoveUsersFromRoles` methods.

In the *Role-Based Authorization* tutorial we will look at ways to programmatically show or hide functionality based on the currently logged in user's role. To accomplish this, we can use the Role class's `FindUsersInRole`, `GetRolesForUser`, `GetUsersInRole`, or `IsUserInRole` methods.

NOTE

Keep in mind that any time one of these methods is invoked, the `Roles` class delegates the call to the configured provider. In our case, this means that the call is being sent to the `SqlRoleProvider`. The `SqlRoleProvider` then performs the appropriate database operation based on the invoked method. For example, the code `Roles.CreateRole("Administrators")` results in the `SqlRoleProvider` executing the `aspnet_Roles_CreateRole` stored procedure, which inserts a new record into the `aspnet_Roles` table named Administrators .

The remainder of this tutorial looks at using the `Roles` class's `CreateRole`, `GetAllRoles`, and `DeleteRole` methods to manage the roles in the system.

Step 4: Creating New Roles

Roles offer a way to arbitrarily group users, and most commonly this grouping is used for a more convenient way to apply authorization rules. But in order to use roles as an authorization mechanism we first need to define what roles exist in the application. Unfortunately, ASP.NET does not include a CreateRoleWizard control. In order to add new roles we need to create a suitable user interface and invoke the Roles API ourselves. The good news is that this is very easy to accomplish.

NOTE

While there is no CreateRoleWizard Web control, there is the ASP.NET Web Site Administration Tool, which is a local ASP.NET application designed to assist with viewing and managing your web application's configuration. However, I am not a big fan of the ASP.NET Web Site Administration Tool for two reasons. First, it is a bit buggy and the user experience leaves a lot to be desired. Second, the ASP.NET Web Site Administration Tool is designed to only work locally, meaning that you will have to build your own role management web pages if you need to manage roles on a live site remotely. For these two reasons, this tutorial and the next will focus on building the necessary role management tools in a web page rather than relying on the ASP.NET Web Site Administration Tool.

Open the `ManageRoles.aspx` page in the `Roles` folder and add a TextBox and a Button Web control to the page. Set the TextBox control's `ID` property to `RoleName` and the Button's `ID` and `Text` properties to `CreateRoleButton` and Create Role, respectively. At this point, your page's declarative markup should look similar to the following:

```
<b>Create a New Role:</b>
<asp:TextBox ID="RoleName" runat="server"></asp:TextBox>
<br />
<asp:Button ID="CreateRoleButton" runat="server" Text="Create Role" />
```

Next, double-click the `CreateRoleButton` Button control in the Designer to create a `Click` event handler and then add the following code:

```
Protected Sub CreateRoleButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
CreateRoleButton.Click
 Dim newRoleName As String = RoleName.Text.Trim()

 If Not Roles.RoleExists(newRoleName) Then
 ' Create the role
 Roles.CreateRole(newRoleName)
 End If

 RoleName.Text= String.Empty
End Sub
```

The above code starts by assigning the trimmed role name entered in the `RoleName` TextBox to the `newRoleName` variable. Next, the `Roles` class's `RoleExists` method is called to determine if the role `newRoleName` already exists in the system. If the role does not exist, it is created via a call to the `CreateRole` method. If the `CreateRole` method is passed a role name that already exists in the system, a `ProviderException` exception is thrown. This is why the code first checks to ensure that the role does not already exist in the system before calling `CreateRole`. The `Click` event handler concludes by clearing out the `RoleName` TextBox's `Text` property.

> **NOTE**
>
> You may be wondering what will happen if the user doesn't enter any value into the `RoleName` TextBox. If the value passed into the `CreateRole` method is `Nothing` or an empty string, an exception is raised. Likewise, if the role name contains a comma an exception is raised. Consequently, the page should contain validation controls to ensure that the user enters a role and that it does not contain any commas. I leave as an exercise for the reader.

Let's create a role named Administrators. Visit the `ManageRoles.aspx` page through a browser, type in Administrators into the textbox (see Figure 3), and then click the Create Role button.

Figure 3: Create an Administrators Role (Click to view full-size image)

What happens? A postback occurs, but there's no visual cue that the role has actually been added to the system. We will update this page in Step 5 to include visual feedback. For now, however, you can verify that the role was created by going to the `SecurityTutorials.mdf` database and displaying the data from the `aspnet_Roles` table. As Figure 4 shows, the `aspnet_Roles` table contains a record for the just-added Administrators roles.

Figure 4: The `aspnet_Roles` Table has a Row for the Administrators (Click to view full-size image)

Step 5: Displaying the Roles in the System

Let's augment the `ManageRoles.aspx` page to include a list of the current roles in the system. To accomplish this, add a GridView control to the page and set its `ID` property to `RoleList`. Next, add a method to the page's code-

behind class named `DisplayRolesInGrid` using the following code:

```
Private Sub DisplayRolesInGrid()
 RoleList.DataSource = Roles.GetAllRoles()
 RoleList.DataBind()
End Sub
```

The `Roles` class's `GetAllRoles` method returns all of the roles in the system as an array of strings. This string array is then bound to the GridView. In order to bind the list of roles to the GridView when the page is first loaded, we need to call the `DisplayRolesInGrid` method from the page's `Page_Load` event handler. The following code calls this method when the page is first visited, but not on subsequent postbacks.

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Not Page.IsPostBack Then
 DisplayRolesInGrid()
 End If
End Sub
```

With this code in place, visit the page through a browser. As Figure 5 shows, you should see a grid with a single column labeled Item. The grid includes a row for the Administrators role we added in Step 4.

Figure 5: The GridView Displays the Roles in a Single Column (Click to view full-size image)

The GridView displays a lone column labeled Item because the GridView's `AutoGenerateColumns` property is set to True (the default), which causes the GridView to automatically create a column for each property in its `DataSource`. An array has a single property that represents the elements in the array, hence the single column in the GridView.

When displaying data with a GridView, I prefer to explicitly define my columns rather than have them implicitly generated by the GridView. By explicitly defining the columns it is much easier to format the data, rearrange the columns, and perform other common tasks. Therefore, let's update the GridView's declarative markup so that its columns are explicitly defined.

Start by setting the GridView's `AutoGenerateColumns` property to False. Next, add a TemplateField to the grid, set its `HeaderText` property to Roles, and configure its `ItemTemplate` so that it displays the contents of the array. To accomplish this, add a Label Web control named `RoleNameLabel` to the `ItemTemplate` and bind its `Text` property to `Container.DataItem.`

These properties and the `ItemTemplate`'s contents can be set declaratively or through the GridView's Fields dialog box and Edit Templates interface. To reach the Fields dialog box, click the Edit Columns link in the GridView's

Smart Tag. Next, uncheck the Auto-generate fields checkbox to set the `AutoGenerateColumns` property to False, and add a TemplateField to the GridView, setting its `HeaderText` property to Role. To define the `ItemTemplate`'s contents, choose the Edit Templates option from the GridView's Smart Tag. Drag a Label Web control onto the `ItemTemplate`, set its `ID` property to `RoleNameLabel`, and configure its databinding settings so that its `Text` property is bound to `Container.DataItem`.

Regardless of what approach you use, the GridView's resulting declarative markup should look similar to the following when you are done.

```
<asp:GridView ID="RoleList" runat="server" AutoGenerateColumns="false">
 <Columns>
 <asp:TemplateField HeaderText="Role">
 <ItemTemplate>
 <asp:Label runat="server" ID="RoleNameLabel" Text='<%# Container.DataItem %>' />
 </ItemTemplate>
 </asp:TemplateField>
 </Columns>
</asp:GridView>
```

NOTE

The array's contents are displayed using the databinding syntax `<%# Container.DataItem %>`. A thorough description of why this syntax is used when displaying the contents of an array bound to the GridView is beyond the scope of this tutorial. For more information on this matter, refer to Binding a Scalar Array to a Data Web Control.

Currently, the `RoleList` GridView is only bound to the list of roles when the page is first visited. We need to refresh the grid whenever a new role is added. To accomplish this, update the `CreateRoleButton` Button's `Click` event handler so that it calls the `DisplayRolesInGrid` method if a new role is created.

```
Protected Sub CreateRoleButton_Click(ByVal sender As Object,ByVal e As System.EventArgs) Handles
CreateRoleButton.Click
 Dim newRoleName As String = RoleName.Text.Trim()

 If Not Roles.RoleExists(newRoleName) Then
 ' Create the role
 Roles.CreateRole(newRoleName)

 ' Refresh the RoleList Grid
 DisplayRolesInGrid()
 End If

 RoleName.Text = String.Empty
End Sub
```

Now when the user adds a new role the `RoleList` GridView shows the just-added role on postback, providing visual feedback that the role was successfully created. To illustrate this, visit the `ManageRoles.aspx` page through a browser and add a role named Supervisors. Upon clicking the Create Role button, a postback will ensue and the grid will update to include Administrators as well as the new role, Supervisors.

Figure 6: The Supervisors Role has Been Added (Click to view full-size image)

Step 6: Deleting Roles

At this point a user can create a new role and view all existing roles from the `ManageRoles.aspx` page. Let's allow users to also delete roles. The `Roles.DeleteRole` method has two overloads:

- `DeleteRole(roleName)` - deletes the role *roleName*. An exception is thrown if the role contains one or more members.
- `DeleteRole(roleName, throwOnPopulatedRole)` - deletes the role *roleName*. If *throwOnPopulateRole* is `True`, then an exception is thrown if the role contains one or more members. If *throwOnPopulateRole* is `False`, then the role is deleted whether it contains any members or not. Internally, the `DeleteRole(roleName)` method calls `DeleteRole(roleName, True)`.

The `DeleteRole` method will also throw an exception if *roleName* is `Nothing` or an empty string or if *roleName* contains a comma. If *roleName* does not exist in the system, `DeleteRole` fails silently, without raising an exception.

Let's augment the GridView in `ManageRoles.aspx` to include a Delete button that, when clicked, deletes the selected role. Start by adding a Delete button to the GridView by going to the Fields dialog box and adding a Delete button, which is located under the CommandField option. Make the Delete button the far left column and set its `DeleteText` property to Delete Role .

Figure 7: Add a Delete Button to the `RoleList` GridView (Click to view full-size image)

After adding the Delete button, your GridView's declarative markup should look similar to the following:

```
<asp:GridView ID="RoleList" runat="server" AutoGenerateColumns="False">
 <Columns>
 <asp:CommandField DeleteText="Delete Role" ShowDeleteButton="True" />
 <asp:TemplateField HeaderText="Role">
 <ItemTemplate>
 <asp:Label runat="server" ID="RoleNameLabel" Text='<%# Container.DataItem %>' />
 </ItemTemplate>
 </asp:TemplateField>
 </Columns>
</asp:GridView>
```

Next, create an event handler for the GridView's `RowDeleting` event. This is the event that is raised on postback when the Delete Role button is clicked. Add the following code to the event handler.

```
Protected Sub RoleList_RowDeleting(ByVal sender As Object,ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs) Handles RoleList.RowDeleting
 ' Get the RoleNameLabel
 Dim RoleNameLabel As Label = CType(RoleList.Rows(e.RowIndex).FindControl("RoleNameLabel"),Label)

 ' Delete the role
 Roles.DeleteRole(RoleNameLabel.Text,False)

 ' Rebind the data to the RoleList grid
 DisplayRolesInGrid()
End Sub
```

The code starts by programmatically referencing the `RoleNameLabel` Web control in the row whose Delete Role button was clicked. The `Roles.DeleteRole` method is then invoked, passing in the `Text` of the `RoleNameLabel` and `False`, thereby deleting the role regardless of whether there are any users associated with the role. Finally, the `RoleList` GridView is refreshed so that the just-deleted role no longer appears in the grid.

NOTE

The Delete Role button does not require any sort of confirmation from the user before deleting the role. One of the easiest ways to confirm an action is through a client-side confirm dialog box. For more information on this technique, see Adding Client-Side Confirmation When Deleting.

Summary

Many web applications have certain authorization rules or page-level functionality that is only available to certain classes of users. For example, there may be a set of web pages that only administrators can access. Rather than defining these authorization rules on a user-by-user basis, oftentimes it is more useful to define the rules based on a role. That is, rather than explicitly allowing users Scott and Jisun to access the administrative web pages, a more maintainable approach is to permit members of the Administrators role to access these pages, and then to denote Scott and Jisun as users belonging to the Administrators role.

The Roles framework makes it easy to create and manage roles. In this tutorial we examined how to configure the Roles framework to use the `SqlRoleProvider`, which uses a Microsoft SQL Server database as the role store. We also created a web page that lists the existing roles in the system and allows for new roles to be created and existing ones to be deleted. In subsequent tutorials we will see how to assign users to roles and how to apply role-based authorization.

Happy Programming!

Assigning Roles to Users (VB)

2/20/2020 • 29 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will build two ASP.NET pages to assist with managing what users belong to what roles. The first page will include facilities to see what users belong to a given role, what roles a particular user belongs to, and the ability to assign or remove a particular user from a particular role. In the second page we will augment the CreateUserWizard control so that it includes a step to specify what roles the newly created user belongs to. This is useful in scenarios where an administrator is able to create new user accounts.

Introduction

The previous tutorial examined the Roles framework and the `SqlRoleProvider`; we saw how to use the `Roles` class to create, retrieve, and delete roles. In addition to creating and deleting roles, we need to be able to assign or remove users from a role. Unfortunately, ASP.NET does not ship with any Web controls for managing what users belong to what roles. Instead, we must create our own ASP.NET pages to manage these associations. The good news is that adding and removing users to roles is quite easy. The `Roles` class contains a number of methods for adding one or more users to one or more roles.

In this tutorial we will build two ASP.NET pages to assist with managing what users belong to what roles. The first page will include facilities to see what users belong to a given role, what roles a particular user belongs to, and the ability to assign or remove a particular user from a particular role. In the second page we will augment the CreateUserWizard control so that it includes a step to specify what roles the newly created user belongs to. This is useful in scenarios where an administrator is able to create new user accounts.

Let's get started!

Listing What Users Belong To What Roles

The first order of business for this tutorial is to create a web page from which users can be assigned to roles. Before we concern ourselves with how to assign users to roles, let's first concentrate on how to determine what users belong to what roles. There are two ways to display this information: "by role" or "by user." We could allow the visitor to select a role and then show them all of the users that belong to the role (the "by role" display), or we could prompt the visitor to select a user and then show them the roles assigned to that user (the "by user" display).

The "by role" view is useful in circumstances where the visitor wants to know the set of users that belong to a particular role; the "by user" view is ideal when the visitor needs to know a particular user's role(s). Let's have our page include both "by role" and "by user" interfaces.

We will start with creating the "by user" interface. This interface will consist of a drop-down list and a list of checkboxes. The drop-down list will be populated with the set of users in the system; the checkboxes will enumerate the roles. Selecting a user from the drop-down list will check those roles the user belongs to. The person visiting the page can then check or uncheck the checkboxes to add or remove the selected user from the corresponding roles.

> **NOTE**
> Using a drop-down list to list the user accounts is not an ideal choice for websites where there may be hundreds of user accounts. A drop-down list is designed to allow a user to pick one item from a relatively short list of options. It quickly becomes unwieldy as the number of list items grows. If you are building a website that will have potentially large numbers of user accounts, you may want to consider using an alternative user interface, such as a pageable GridView or a filterable interface that lists prompts the visitor to choose a letter and then only shows those users whose username starts with the selected letter.

Step 1: Building the "By User" User Interface

Open the `UsersAndRoles.aspx` page. At the top of the page, add a Label Web control named `ActionStatus` and clear out its `Text` property. We will use this Label to provide feedback on the actions performed, displaying messages like, "User Tito has been added to the Administrators role," or "User Jisun has been removed from the Supervisors role." In order to make these messages stand out, set the Label's `CssClass` property to "Important".

```
<p align="center">
     <asp:Label ID="ActionStatus" runat="server" CssClass="Important"> </asp:Label>
</p>
```

Next, add the following CSS class definition to the `Styles.css` stylesheet:

```
.Important
{
     font-size: large;
     color: Red;
}
```

This CSS definition instructs the browser to display the Label using a large, red font. Figure 1 shows this effect through the Visual Studio Designer.

Figure 1: The Label's `CssClass` Property Results in a Large, Red Font (Click to view full-size image)

Next, add a DropDownList to the page, set its `ID` property to `UserList`, and set its `AutoPostBack` property to True. We will use this DropDownList to list all of the users in the system. This DropDownList will be bound to a collection of MembershipUser objects. Because we want the DropDownList to display the UserName property of the MembershipUser object (and use it as the value of the list items), set the DropDownList's `DataTextField` and `DataValueField` properties to "UserName".

Underneath the DropDownList, add a Repeater named `UsersRoleList`. This Repeater will list all of the roles in the system as a series of checkboxes. Define the Repeater's `ItemTemplate` using the following declarative markup:

```
<asp:Repeater ID="UsersRoleList" runat="server">
     <ItemTemplate>
          <asp:CheckBox runat="server" ID="RoleCheckBox" AutoPostBack="true"
               Text='<%# Container.DataItem %>' />
          <br />
     </ItemTemplate>
</asp:Repeater>
```

The `ItemTemplate` markup includes a single CheckBox Web control named `RoleCheckBox`. The CheckBox's `AutoPostBack` property is set to True and the `Text` property is bound to `Container.DataItem`. The reason the databinding syntax is simply `Container.DataItem` is because the Roles framework returns the list of role names as a string array, and it is this string array that we will be binding to the Repeater. A thorough description of why this syntax is used to display the contents of an array bound to a data Web control is beyond the scope of this tutorial. For more information on this matter, refer to Binding a Scalar Array to a Data Web Control.

At this point your "by user" interface's declarative markup should look similar to the following:

```
<h3>Manage Roles By User</h3>
<p>
     <b>Select a User:</b>
     <asp:DropDownList ID="UserList" runat="server" AutoPostBack="True"
          DataTextField="UserName" DataValueField="UserName">
     </asp:DropDownList>
</p>
<p>
     <asp:Repeater ID="UsersRoleList" runat="server">
          <ItemTemplate>
               <asp:CheckBox runat="server" ID="RoleCheckBox" AutoPostBack="true"
                    Text='<%# Container.DataItem %>' />
               <br />
          </ItemTemplate>
     </asp:Repeater>
</p>
```

We are now ready to write the code to bind the set of user accounts to the DropDownList and the set of roles to the Repeater. In the page's code-behind class, add a method named `BindUsersToUserList` and another named `BindRolesList`, using the following code:

```
Private Sub BindUsersToUserList()
     ' Get all of the user accounts
     Dim users As MembershipUserCollection = Membership.GetAllUsers()
     UserList.DataSource = users
     UserList.DataBind()
End Sub

Private Sub BindRolesToList()
     ' Get all of the roles
     Dim roleNames() As String = Roles.GetAllRoles()
     UsersRoleList.DataSource = roleNames
     UsersRoleList.DataBind()
End Sub
```

The `BindUsersToUserList` method retrieves all of the user accounts in the system via the `Membership.GetAllUsers` method. This returns a `MembershipUserCollection` object, which is a collection of `MembershipUser` instances. This collection is then bound to the `UserList` DropDownList. The `MembershipUser` instances that makeup the collection contain a variety of properties, like `UserName`, `Email`, `CreationDate`, and `IsOnline`. In order to instruct

the DropDownList to display the value of the `UserName` property, ensure that the `UserList` DropDownList's `DataTextField` and `DataValueField` properties have been set to "UserName".

> **NOTE**
>
> The `Membership.GetAllUsers` method has two overloads: one that accepts no input parameters and returns all of the users, and one that takes in integer values for the page index and page size, and returns only the specified subset of the users. When there are large amounts of user accounts being displayed in a pageable user interface element, the second overload can be used to more efficiently page through the users since it returns just the precise subset of user accounts rather than all of them.

The `BindRolesToList` method starts by calling the `Roles` class's `GetAllRoles` method, which returns a string array containing the roles in the system. This string array is then bound to the Repeater.

Finally, we need to call these two methods when the page is first loaded. Add the following code to the `Page_Load` event handler:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
     If Not Page.IsPostBack Then
          ' Bind the users and roles
          BindUsersToUserList()
          BindRolesToList()
     End If
End Sub
```

With this code in place, take a moment to visit the page through a browser; your screen should look similar to Figure 2. All of the user accounts are populated in the drop-down list and, underneath that, each role appears as a checkbox. Because we set the `AutoPostBack` properties of the DropDownList and CheckBoxes to True, changing the selected user or checking or unchecking a role causes a postback. No action is performed, however, because we have yet to write code to handle these actions. We'll tackle these tasks in the next two sections.

Figure 2: The Page Displays the Users and Roles (Click to view full-size image)

Checking the Roles the Selected User Belongs To

When the page is first loaded, or whenever the visitor selects a new user from the drop-down list, we need to update the `UsersRoleList`'s checkboxes so that a given role checkbox is checked only if the selected user belongs to that role. To accomplish this, create a method named `CheckRolesForSelectedUser` with the following code:

```
Private Sub CheckRolesForSelectedUser()
     ' Determine what roles the selected user belongs to
     Dim selectedUserName As String = UserList.SelectedValue
     Dim selectedUsersRoles() As String = Roles.GetRolesForUser(selectedUserName)

     ' Loop through the Repeater's Items and check or uncheck the checkbox as needed
     For Each ri As RepeaterItem In UsersRoleList.Items
          ' Programmatically reference the CheckBox
          Dim RoleCheckBox As CheckBox = CType(ri.FindControl("RoleCheckBox"), CheckBox)
          ' See if RoleCheckBox.Text is in selectedUsersRoles
          If Linq.Enumerable.Contains(Of String)(selectedUsersRoles, RoleCheckBox.Text) Then
               RoleCheckBox.Checked = True
          Else
               RoleCheckBox.Checked = False
          End If
     Next
End Sub
```

The above code starts by determining who the selected user is. It then uses the Roles class's `GetRolesForUser(userName)` method to return the specified user's set of roles as a string array. Next, the Repeater's items are enumerated and each item's `RoleCheckBox` CheckBox is programmatically referenced. The CheckBox is checked only if the role it corresponds to is contained within the `selectedUsersRoles` string array.

> **NOTE**
> The `Linq.Enumerable.Contains(Of String)(...)` syntax will not compile if you are using ASP.NET version 2.0. The `Contains(Of String)` method is part of the LINQ library, which is new to ASP.NET 3.5. If you are still using ASP.NET version 2.0, use the `Array.IndexOf(Of String)` method instead.

The `CheckRolesForSelectedUser` method needs to be called in two cases: when the page is first loaded and whenever the `UserList` DropDownList's selected index is changed. Therefore, call this method from the `Page_Load` event handler (after the calls to `BindUsersToUserList` and `BindRolesToList`). Also, create an event handler for the DropDownList's `SelectedIndexChanged` event and call this method from there.

```
Protected Sub Page_Load(ByVal sender As Object,ByVal e As System.EventArgs) Handles Me.Load
     If Not Page.IsPostBack Then
          ' Bind the users and roles
          BindUsersToUserList()
          BindRolesToList()
          ' Check the selected user's roles
          CheckRolesForSelectedUser()
     End If
End Sub

...

Protected Sub UserList_SelectedIndexChanged(ByVal sender As Object,ByVal e As System.EventArgs) Handles
UserList.SelectedIndexChanged
     CheckRolesForSelectedUser()
End Sub
```

With this code in place, you can test the page through the browser. However, since the `UsersAndRoles.aspx` page currently lacks the ability to assign users to roles, no users have roles. We will create the interface for assigning users to roles in a moment, so you can either take my word that this code works and verify that it does so later, or you can manually add users to roles by inserting records into the `aspnet_UsersInRoles` table in order to test this functionality now.

Assigning and Removing Users from Roles

When the visitor checks or unchecks a CheckBox in the `UsersRoleList` Repeater we need to add or remove the selected user from the corresponding role. The CheckBox's `AutoPostBack` property is currently set to True, which causes a postback anytime a CheckBox in the Repeater is checked or unchecked. In short, we need to create an event handler for the CheckBox's `CheckChanged` event. Since the CheckBox is in a Repeater control, we need to manually add the event handler plumbing. Start by adding the event handler to the code-behind class as a `Protected` method, like so:

```
Protected Sub RoleCheckBox_CheckChanged(ByVal sender As Object, ByVal e As EventArgs)

End Sub
```

We will return to write the code for this event handler in a moment. But first let's complete the event handling plumbing. From the CheckBox within the Repeater's `ItemTemplate`, add `OnCheckedChanged="RoleCheckBox_CheckChanged"`. This syntax wires the `RoleCheckBox_CheckChanged` event handler to the `RoleCheckBox`'s `CheckedChanged` event.

```
<asp:CheckBox runat="server" ID="RoleCheckBox"
     AutoPostBack="true"
     Text='<%# Container.DataItem %>'
     OnCheckedChanged="RoleCheckBox_CheckChanged" />
```

Our final task is to complete the `RoleCheckBox_CheckChanged` event handler. We need to start by referencing the CheckBox control that raised the event because this CheckBox instance tells us what role was checked or unchecked via its `Text` and `Checked` properties. Using this information along with the UserName of the selected user, we add or remove the user from the role via the `Roles` class's `AddUserToRole` or `RemoveUserFromRole` method.

```
Protected Sub RoleCheckBox_CheckChanged(ByVal sender As Object, ByVal e As EventArgs)
     'Reference the CheckBox that raised this event
     Dim RoleCheckBox As CheckBox = CType(sender, CheckBox)

     ' Get the currently selected user and role
     Dim selectedUserName As String = UserList.SelectedValue
     Dim roleName As String = RoleCheckBox.Text

     ' Determine if we need to add or remove the user from this role
     If RoleCheckBox.Checked Then
          ' Add the user to the role
          Roles.AddUserToRole(selectedUserName, roleName)
          ' Display a status message
          ActionStatus.Text = String.Format("User {0} was added to role {1}.", selectedUserName,roleName)
     Else
          ' Remove the user from the role
          Roles.RemoveUserFromRole(selectedUserName, roleName)
          ' Display a status message
          ActionStatus.Text = String.Format("User {0} was removed from role {1}.", selectedUserName,roleName)
     End If
End Sub
```

The above code starts by programmatically referencing the CheckBox that raised the event, which is available via the `sender` input parameter. If the CheckBox is checked, the selected user is added to the specified role, otherwise they are removed from the role. In either case, the `ActionStatus` Label displays a message summarizing the action just performed.

Take a moment to test out this page through a browser. Select user Tito and then add Tito to both the Administrators and Supervisors roles.

Figure 3: Tito Has Been Added to the Administrators and Supervisors Roles (Click to view full-size image)

Next, select user Bruce from the drop-down list. There is a postback and the Repeater's CheckBoxes are updated via the `CheckRolesForSelectedUser`. Since Bruce does not yet belong to any roles, the two checkboxes are unchecked. Next, add Bruce to the Supervisors role.

Figure 4: Bruce Has Been Added to the Supervisors Role (Click to view full-size image)

To further verify the functionality of the `CheckRolesForSelectedUser` method, select a user other than Tito or Bruce. Note how the checkboxes are automatically unchecked, denoting that they do not belong to any roles. Return to Tito. Both the Administrators and Supervisors checkboxes should be checked.

Step 2: Building the "By Roles" User Interface

At this point we have completed the "by users" interface and are ready to start tackling the "by roles" interface. The "by roles" interface prompts the user to select a role from a drop-down list and then displays the set of users that belong to that role in a GridView.

Add another DropDownList control to the `UsersAndRoles.aspx page`. Place this one beneath the Repeater control, name it `RoleList`, and set its `AutoPostBack` property to True. Underneath that, add a GridView and name it `RolesUserList`. This GridView will list the users that belong to the selected role. Set the GridView's `AutoGenerateColumns` property to False, add a TemplateField to the grid's `Columns` collection, and set its `HeaderText` property to "Users". Define the TemplateField's `ItemTemplate` so that it displays the value of the

databinding expression `Container.DataItem` in the `Text` property of a Label named `UserNameLabel`.

After adding and configuring the GridView, your "by role" interface's declarative markup should look similar to the following:

```
<h3>Manage Users By Role</h3>
<p>
     <b>Select a Role:</b>
     <asp:DropDownList ID="RoleList" runat="server" AutoPostBack="true"></asp:DropDownList>
</p>
<p>
     <asp:GridView ID="RolesUserList" runat="server" AutoGenerateColumns="false"
          EmptyDataText="No users belong to this role.">
          <Columns>
               <asp:TemplateField HeaderText="Users">
                    <ItemTemplate>
                         <asp:Label runat="server" id="UserNameLabel"
                              Text='<%# Container.DataItem %>'></asp:Label>
                    </ItemTemplate>
               </asp:TemplateField>
          </Columns>
     </asp:GridView>
</p>
```

We need to populate the `RoleList` DropDownList with the set of roles in the system. To accomplish this, update the `BindRolesToList` method so that is binds the string array returned by the `Roles.GetAllRoles` method to the `RolesList` DropDownList (as well as the `UsersRoleList` Repeater).

```
Private Sub BindRolesToList()
     ' Get all of the roles
     Dim roleNames() As String = Roles.GetAllRoles()
     UsersRoleList.DataSource = roleNames
     UsersRoleList.DataBind()

     RoleList.DataSource = roleNames
     RoleList.DataBind()
End Sub
```

The last two lines in the `BindRolesToList` method have been added to bind the set of roles to the `RoleList` DropDownList control. Figure 5 shows the end result when viewed through a browser – a drop-down list populated with the system's roles.

Figure 5: The Roles are Displayed in the `RoleList` DropDownList (Click to view full-size image)

Displaying the Users That Belong To the Selected Role

When the page is first loaded, or when a new role is selected from the `RoleList` DropDownList, we need to display the list of users that belong to that role in the GridView. Create a method named `DisplayUsersBelongingToRole` using the following code:

```
Private Sub DisplayUsersBelongingToRole()
     ' Get the selected role
     Dim selectedRoleName As String = RoleList.SelectedValue

     ' Get the list of usernames that belong to the role
     Dim usersBelongingToRole() As String = Roles.GetUsersInRole(selectedRoleName)

     ' Bind the list of users to the GridView
     RolesUserList.DataSource = usersBelongingToRole
     RolesUserList.DataBind()
End Sub
```

This method starts by getting the selected role from the `RoleList` DropDownList. It then uses the `Roles.GetUsersInRole(roleName)` method to retrieve a string array of the UserNames of the users that belong to that role. This array is then bound to the `RolesUserList` GridView.

This method needs to be called in two circumstances: when the page is initially loaded and when the selected role in the `RoleList` DropDownList changes. Therefore, update the `Page_Load` event handler so that this method is invoked after the call to `CheckRolesForSelectedUser`. Next, create an event handler for the `RoleList`'s `SelectedIndexChanged` event, and call this method from there, too.

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
     If Not Page.IsPostBack Then
          ' Bind the users and roles
          BindUsersToUserList()
          BindRolesToList()

          ' Check the selected user's roles
          CheckRolesForSelectedUser()

          'Display those users belonging to the currently selected role
          DisplayUsersBelongingToRole()
     End If
End Sub

...

Protected Sub RoleList_SelectedIndexChanged(ByVal sender As Object, ByVal e As System.EventArgs) Handles
RoleList.SelectedIndexChanged
     DisplayUsersBelongingToRole()
End Sub
```

With this code in place, the `RolesUserList` GridView should display those users that belong to the selected role. As Figure 6 shows, the Supervisors role consists of two members: Bruce and Tito.

Figure 6: The GridView Lists Those Users That Belong to the Selected Role (Click to view full-size image)

Removing Users from the Selected Role

Let's augment the `RolesUserList` GridView so that it includes a column of "Remove" buttons. Clicking the "Remove" button for a particular user will remove them from that role.

Start by adding a Delete button field to the GridView. Make this field appear as the left most filed and change its `DeleteText` property from "Delete" (the default) to "Remove".

Figure 7: Add the "Remove" Button to the GridView (Click to view full-size image)

When the "Remove" button is clicked a postback ensues and the GridView's `RowDeleting` event is raised. We need to create an event handler for this event and write code that removes the user from the selected role. Create the event handler and then add the following code:

```
Protected Sub RolesUserList_RowDeleting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs) Handles RolesUserList.RowDeleting
     ' Get the selected role
     Dim selectedRoleName As String = RoleList.SelectedValue

     ' Reference the UserNameLabel
     Dim UserNameLabel As Label = CType(RolesUserList.Rows(e.RowIndex).FindControl("UserNameLabel"),Label)

     ' Remove the user from the role
     Roles.RemoveUserFromRole(UserNameLabel.Text, selectedRoleName)

     ' Refresh the GridView
     DisplayUsersBelongingToRole()

     ' Display a status message
     ActionStatus.Text = String.Format("User {0} was removed from role {1}.",
UserNameLabel.Text,selectedRoleName)
End Sub
```

The code starts by determining the selected role name. It then programmatically references the `UserNameLabel` control from the row whose "Remove" button was clicked in order to determine the UserName of the user to remove. The user is then removed from the role via a call to the `Roles.RemoveUserFromRole` method. The `RolesUserList` GridView is then refreshed and a message is displayed via the `ActionStatus` Label control.

> **NOTE**
>
> The "Remove" button does not require any sort of confirmation from the user before removing the user from the role. I invite you to add some level of user confirmation. One of the easiest ways to confirm an action is through a client-side confirm dialog box. For more information on this technique, see Adding Client-Side Confirmation When Deleting.

Figure 8 shows the page after user Tito has been removed from the Supervisors group.

Figure 8: Alas, Tito is No Longer a Supervisor (Click to view full-size image)

Adding New Users to the Selected Role

Along with removing users from the selected role, the visitor to this page should also be able to add a user to the selected role. The best interface for adding a user to the selected role depends on the number of user accounts

you expect to have. If your website will house just a few dozen user accounts or less, you could use a DropDownList here. If there might be thousands of user accounts, you would want to include a user interface that permits the visitor to page through the accounts, search for a particular account, or filter the user accounts in some other fashion.

For this page let's use a very simple interface that works regardless of the number of user accounts in the system. Namely, we will use a TextBox, prompting the visitor to type in the username of the user she wants to add to the selected role. If no user with that name exists, or if the user is already a member of the role, we'll display a message in `ActionStatus` Label. But if the user exists and is not a member of the role, we'll add them to the role and refresh the grid.

Add a TextBox and Button beneath the GridView. Set the TextBox's `ID` to `UserNameToAddToRole` and set the Button's `ID` and `Text` properties to `AddUserToRoleButton` and "Add User to Role", respectively.

```
<p>
     <b>UserName:</b>
     <asp:TextBox ID="UserNameToAddToRole" runat="server"></asp:TextBox>
     <br />
     <asp:Button ID="AddUserToRoleButton" runat="server" Text="Add User to Role" />
</p>
```

Next, create a `Click` event handler for the `AddUserToRoleButton` and add the following code:

```
Protected Sub AddUserToRoleButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
AddUserToRoleButton.Click
     ' Get the selected role and username
     Dim selectedRoleName As String = RoleList.SelectedValue
     Dim userToAddToRole As String = UserNameToAddToRole.Text

     ' Make sure that a value was entered
     If userToAddToRole.Trim().Length = 0 Then
          ActionStatus.Text = "You must enter a username in the textbox."
          Exit Sub
     End If

     ' Make sure that the user exists in the system
     Dim userInfo As MembershipUser = Membership.GetUser(userToAddToRole)
     If userInfo Is Nothing Then
          ActionStatus.Text = String.Format("The user {0} does not exist in the system.",userNameToAddToRole)
          Exit Sub
     End If

     ' Make sure that the user doesn't already belong to this role
     If Roles.IsUserInRole(userToAddToRole, selectedRoleName) Then
          ActionStatus.Text = String.Format("User {0} already is a member of role {1}.",
UserNameToAddToRole,selectedRoleName)
          Exit Sub
     End If

     ' If we reach here, we need to add the user to the role
     Roles.AddUserToRole(userToAddToRole, selectedRoleName)

     ' Clear out the TextBox
     userNameToAddToRole.Text = String.Empty

     ' Refresh the GridView
     DisplayUsersBelongingToRole()

     ' Display a status message
     ActionStatus.Text = String.Format("User {0} was added to role {1}.",
UserNameToAddToRole,selectedRoleName)
End Sub
```

The majority of the code in the `Click` event handler performs various validation checks. It ensures that the visitor supplied a username in the `UserNameToAddToRole` TextBox, that the user exists in the system, and that they don't already belong to the selected role. If any of these checks fails, an appropriate message is displayed in `ActionStatus` and the event handler is exited. If all of the checks pass, the user is added to the role via the `Roles.AddUserToRole` method. Following that, the TextBox's `Text` property is cleared out, the GridView is refreshed, and the `ActionStatus` Label displays a message indicating that the specified user was successfully added to the selected role.

NOTE

To ensure that the specified user does not already belong to the selected role, we use the `Roles.IsUserInRole(userName, roleName)` method, which returns a Boolean value indicating whether *userName* is a member of *roleName*. We will use this method again in the next tutorial when we look at role-based authorization.

Visit the page through a browser and select the Supervisors role from the `RoleList` DropDownList. Try entering an invalid username – you should see a message explaining that the user does not exist in the system.

Figure 9: You Cannot Add a Non-Existent User to a Role (Click to view full-size image)

Now try adding a valid user. Go ahead and re-add Tito to the Supervisors role.

Figure 10: Tito Is Once Again a Supervisor! (Click to view full-size image)

Step 3: Cross-Updating the "By User" and "By Role" Interfaces

The `UsersAndRoles.aspx` page offers two distinct interfaces for managing users and roles. Currently, these two interfaces act independently of one another so it is possible that a change made in one interface will not be reflected immediately in the other. For example, imagine that the visitor to the page selects the Supervisors role from the `RoleList` DropDownList, which lists Bruce and Tito as its members. Next, the visitor selects Tito from the `UserList` DropDownList, which checks the Administrators and Supervisors checkboxes in the `UsersRoleList` Repeater. If the visitor then unchecks the Supervisor role from the Repeater, Tito is removed from the Supervisors role, but this modification is not reflected in the "by role" interface. The GridView will still show Tito as being a

member of the Supervisors role.

To fix this we need to refresh the GridView whenever a role is checked or unchecked from the `UsersRoleList` Repeater. Likewise, we need to refresh the Repeater whenever a user is removed or added to a role from the "by role" interface.

The Repeater in the "by user" interface is refreshed by calling the `CheckRolesForSelectedUser` method. The "by role" interface can be modified in the `RolesUserList` GridView's `RowDeleting` event handler and the `AddUserToRoleButton` Button's `Click` event handler. Therefore, we need to call the `CheckRolesForSelectedUser` method from each of these methods.

```
Protected Sub RolesUserList_RowDeleting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs) Handles RolesUserList.RowDeleting
     ... Code removed for brevity ...

     ' Refresh the "by user" interface
     CheckRolesForSelectedUser()
End Sub

Protected Sub AddUserToRoleButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
AddUserToRoleButton.Click
     ... Code removed for brevity ...

     ' Refresh the "by user" interface
     CheckRolesForSelectedUser()
End Sub
```

Similarly, the GridView in the "by role" interface is refreshed by calling the `DisplayUsersBelongingToRole` method and the "by user" interface is modified through the `RoleCheckBox_CheckChanged` event handler. Therefore, we need to call the `DisplayUsersBelongingToRole` method from this event handler.

```
Protected Sub RoleCheckBox_CheckChanged(ByVal sender As Object, ByVal e As EventArgs)
     ... Code removed for brevity ...

     ' Refresh the "by role" interface
     DisplayUsersBelongingToRole()
End Sub
```

With these minor code changes, the "by user" and "by role" interfaces now correctly cross-update. To verify this, visit the page through a browser and select Tito and Supervisors from the `UserList` and `RoleList` DropDownLists, respectively. Note that as you uncheck the Supervisors role for Tito from the Repeater in the "by user" interface, Tito is automatically removed from the GridView in the "by role" interface. Adding Tito back to the Supervisors role from the "by role" interface automatically re-checks the Supervisors checkbox in the "by user" interface.

Step 4: Customizing the CreateUserWizard to Include a "Specify Roles" Step

In the *Creating User Accounts* tutorial we saw how to use the CreateUserWizard Web control to provide an interface for creating a new user account. The CreateUserWizard control can be used in one of two ways:

- As a means for visitors to create their own user account on the site, and
- As a means for administrators to create new accounts

In the first use case, a visitor comes to the site and fills out the CreateUserWizard, entering their information in order to register on the site. In the second case, an administrator creates a new account for another person.

When an account is being created by an administrator for some other person, it might be helpful to allow the administrator to specify what roles the new user account belongs to. In the *Storing Additional User Information* tutorial we saw how to customize the CreateUserWizard by adding additional `WizardSteps`. Let's look at how to add an additional step to the CreateUserWizard in order to specify the new user's roles.

Open the `CreateUserWizardWithRoles.aspx` page and add a CreateUserWizard control named `RegisterUserWithRoles`. Set the control's `ContinueDestinationPageUrl` property to "~/Default.aspx". Because the idea here is that an administrator will be using this CreateUserWizard control to create new user accounts, set the control's `LoginCreatedUser` property to False. This `LoginCreatedUser` property specifies whether the visitor is automatically logged on as the just-created user, and it defaults to True. We set it to False because when an administrator creates a new account we want to keep him signed in as himself.

Next, select the "Add/Remove `WizardSteps`..." option from the CreateUserWizard's Smart Tag and add a new `WizardStep`, setting its `ID` to `SpecifyRolesStep`. Move the `SpecifyRolesStep WizardStep` so that it comes after the "Sign Up for Your New Account" step, but before the "Complete" step. Set the `WizardStep`'s `Title` property to "Specify Roles", its `StepType` property to `Step`, and its `AllowReturn` property to False.

Figure 11: Add the "Specify Roles" `WizardStep` to the CreateUserWizard (Click to view full-size image)

After this change your CreateUserWizard's declarative markup should look like the following:

```
<asp:CreateUserWizard ID="RegisterUserWithRoles" runat="server"
     ContinueDestinationPageUrl="~/Default.aspx" LoginCreatedUser="False">
     <WizardSteps>
          <asp:CreateUserWizardStep ID="CreateUserWizardStep1" runat="server">
          </asp:CreateUserWizardStep>
          <asp:WizardStep ID="SpecifyRolesStep" runat="server" StepType="Step"
               Title="Specify Roles" AllowReturn="False">
          </asp:WizardStep>
          <asp:CompleteWizardStep ID="CompleteWizardStep1" runat="server">
          </asp:CompleteWizardStep>
     </WizardSteps>
</asp:CreateUserWizard>
```

In the "Specify Roles" `WizardStep`, add a CheckBoxList named `RoleList.` This CheckBoxList will list the available roles, enabling the person visiting the page to check what roles the newly created user belongs to.

We are left with two coding tasks: first we must populate the `RoleList` CheckBoxList with the roles in the system; second, we need to add the created user to the selected roles when the user moves from the "Specify Roles" step to the "Complete" step. We can accomplish the first task in the `Page_Load` event handler. The following code

programmatically references the `RoleList` CheckBox on the first visit to the page and binds the roles in the system to it.

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
     If Not Page.IsPostBack Then
          ' Reference the SpecifyRolesStep WizardStep
          Dim SpecifyRolesStep As WizardStep =
CType(RegisterUserWithRoles.FindControl("SpecifyRolesStep"),WizardStep)

          ' Reference the RoleList CheckBoxList
          Dim RoleList As CheckBoxList = CType(SpecifyRolesStep.FindControl("RoleList"), CheckBoxList)

          ' Bind the set of roles to RoleList
          RoleList.DataSource = Roles.GetAllRoles()
          RoleList.DataBind()
     End If
End Sub
```

The above code should look familiar. In the *Storing Additional User Information* tutorial we used two `FindControl` statements to reference a Web control from within a custom `WizardStep`. And the code that binds the roles to the CheckBoxList was taken from earlier in this tutorial.

In order to perform the second programming task we need to know when the "Specify Roles" step has been completed. Recall that the CreateUserWizard has an `ActiveStepChanged` event, which fires each time the visitor navigates from one step to another. Here we can determine if the user has reached the "Complete" step; if so, we need to add the user to the selected roles.

Create an event handler for the `ActiveStepChanged` event and add the following code:

```
Protected Sub RegisterUserWithRoles_ActiveStepChanged(ByVal sender As Object, ByVal e As System.EventArgs)
Handles RegisterUserWithRoles.ActiveStepChanged
     'Have we JUST reached the Complete step?
     If RegisterUserWithRoles.ActiveStep.Title = "Complete" Then
          ' Reference the SpecifyRolesStep WizardStep
          Dim SpecifyRolesStep As WizardStep =
CType(RegisterUserWithRoles.FindControl("SpecifyRolesStep"),WizardStep)

          ' Reference the RoleList CheckBoxList
          Dim RoleList As CheckBoxList = CType(SpecifyRolesStep.FindControl("RoleList"), CheckBoxList)

          ' Add the checked roles to the just-added user
          For Each li As ListItem In RoleList.Items
               If li.Selected Then
                    Roles.AddUserToRole(RegisterUserWithRoles.UserName, li.Text)
               End If
          Next
     End If
End Sub
```

If the user has just reached the "Completed" step, the event handler enumerates the items of the `RoleList` CheckBoxList and the just-created user is assigned to the selected roles.

Visit this page through a browser. The first step in the CreateUserWizard is the standard "Sign Up for Your New Account" step, which prompts for the new user's username, password, email, and other key information. Enter the information to create a new user named Wanda.

Figure 12: Create a New User Named Wanda (Click to view full-size image)

Click the "Create User" button. The CreateUserWizard internally calls the `Membership.CreateUser` method, creating the new user account, and then progresses to the next step, "Specify Roles." Here the system roles are listed. Check the Supervisors checkbox and click Next.

Figure 13: Make Wanda a Member of the Supervisors Role (Click to view full-size image)

Clicking Next causes a postback and updates the `ActiveStep` to the "Complete" step. In the `ActiveStepChanged` event handler, the recently-created user account is assigned to the Supervisors role. To verify this, return to the `UsersAndRoles.aspx` page and select Supervisors from the `RoleList` DropDownList. As Figure 14 shows, the Supervisors are now made up of three users: Bruce, Tito, and Wanda.

Figure 14: Bruce, Tito, and Wanda are All Supervisors (Click to view full-size image)

Summary

The Roles framework offers methods for retrieving information about a particular user's roles and methods for determining what users belong to a specified role. Furthermore, there are a number of methods for adding and removing one or more users to one or more roles. In this tutorial we focused on just two of these methods: `AddUserToRole` and `RemoveUserFromRole`. There are additional variants designed to add multiple users to a single role and to assign multiple roles to a single user.

This tutorial also included a look at extending the CreateUserWizard control to include a `WizardStep` to specify the newly-created user's roles. Such a step could help an administrator streamline the process of creating user accounts for new users.

At this point we have seen how to create and delete roles and how to add and remove users from roles. But we have yet to look at applying role-based authorization. In the following tutorial we will look at defining URL authorization rules on a role-by-role basis, as well as how to limit page-level functionality based on the currently logged in user's roles.

Happy Programming!

Role-Based Authorization (VB)

2/20/2020 • 34 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

This tutorial starts with a look at how the Roles framework associates a user's roles with his security context. It then examines how to apply role-based URL authorization rules. Following that, we will look at using declarative and programmatic means for altering the data displayed and the functionality offered by an ASP.NET page.

Introduction

In the *User-Based Authorization* tutorial we saw how to use URL authorization to specify what users could visit a particular set of pages. With just a little bit of markup in `Web.config`, we could instruct ASP.NET to allow only authenticated users to visit a page. Or we could dictate that only users Tito and Bob were allowed, or indicate that all authenticated users except for Sam were permitted.

In addition to URL authorization, we also looked at declarative and programmatic techniques for controlling the data displayed and the functionality offered by a page based on the user visiting. In particular, we created a page that listed the contents of the current directory. Anyone could visit this page, but only authenticated users could view the files' contents and only Tito could delete the files.

Applying authorization rules on a user-by-user basis can grow into a bookkeeping nightmare. A more maintainable approach is to use role-based authorization. The good news is that the tools at our disposal for applying authorization rules work equally well with roles as they do for user accounts. URL authorization rules can specify roles instead of users. The LoginView control, which renders different output for authenticated and anonymous users, can be configured to display different content based on the logged in user's roles. And the Roles API includes methods for determining the logged in user's roles.

This tutorial starts with a look at how the Roles framework associates a user's roles with his security context. It then examines how to apply role-based URL authorization rules. Following that, we will look at using declarative and programmatic means for altering the data displayed and the functionality offered by an ASP.NET page. Let's get started!

Understanding How Roles are Associated with a User's Security Context

Whenever a request enters the ASP.NET pipeline it is associated with a security context, which includes information identifying the requestor. When using forms authentication, an authentication ticket is used as an identity token. As we discussed in the *An Overview of Forms Authentication* and *Forms Authentication Configuration and Advanced Topics* tutorials, the `FormsAuthenticationModule` is responsible for determining the identity of the requestor, which it does during the `AuthenticateRequest` event.

If a valid, non-expired authentication ticket is found, the `FormsAuthenticationModule` decodes it to ascertain the requestor's identity. It creates a new `GenericPrincipal` object and assigns this to the `HttpContext.User` object. The purpose of a principal, like `GenericPrincipal`, is to identify the authenticated user's name and what roles she belong to. This purpose is evident by the fact that all principal objects have an `Identity` property and an `IsInRole(roleName)` method. The `FormsAuthenticationModule`, however, is not interested in recording role

information and the `GenericPrincipal` object it creates does not specify any roles.

If the Roles framework is enabled, the `RoleManagerModule` HTTP Module steps in after the `FormsAuthenticationModule` and identifies the authenticated user's roles during the `PostAuthenticateRequest` event, which fires after the `AuthenticateRequest` event. If the request is from an authenticated user, the `RoleManagerModule` overwrites the `GenericPrincipal` object created by the `FormsAuthenticationModule` and replaces it with a `RolePrincipal` object. The `RolePrincipal` class uses the Roles API to determine what roles the user belongs to.

Figure 1 depicts the ASP.NET pipeline workflow when using forms authentication and the Roles framework. The `FormsAuthenticationModule` executes first, identifies the user via her authentication ticket, and creates a new `GenericPrincipal` object. Next, the `RoleManagerModule` steps in and overwrites the `GenericPrincipal` object with a `RolePrincipal` object.

If an anonymous user visits the site, neither the `FormsAuthenticationModule` nor the `RoleManagerModule` creates a principal object.

Figure 1: The ASP.NET Pipeline Events for an Authenticated User When Using Forms Authentication and the Roles Framework (Click to view full-size image)

Caching Role Information in a Cookie

The `RolePrincipal` object's `IsInRole(roleName)` method calls `Roles`.`GetRolesForUser` to get the roles for the user in order to determine whether the user is a member of *roleName*. When using the `SqlRoleProvider`, this results in a query to the role store database. When using role-based URL authorization rules the `RolePrincipal`'s `IsInRole` method will be called on every request to a page that is protected by the role-based URL authorization rules. Rather than have to lookup the role information in the database on every request, the `Roles` framework includes an option to cache the user's roles in a cookie.

If the Roles framework is configured to cache the user's roles in a cookie, the `RoleManagerModule` creates the cookie during the ASP.NET pipeline's `EndRequest` event. This cookie is used in subsequent requests in the `PostAuthenticateRequest`, which is when the `RolePrincipal` object is created. If the cookie is valid and has not expired, the data in the cookie is parsed and used to populate the user's roles, thereby saving the `RolePrincipal` from having to make a call to the `Roles` class to determine the user's roles. Figure 2 depicts this workflow.

Figure 2: The User's Role Information Can Be Stored in a Cookie to Improve Performance (Click to view full-size image)

By default, the role cache cookie mechanism is disabled. It can be enabled through the `<roleManager>`; configuration markup in `Web.config`. We discussed using the `<roleManager>` element to specify Role providers in the *Creating and Managing Roles* tutorial, so you should already have this element in your application's `Web.config` file. The role cache cookie settings are specified as attributes of the `<roleManager>`; element, and are summarized in Table 1.

> **NOTE**
>
> The configuration settings listed in Table 1 specify the properties of the resulting role cache cookie. For more information on cookies, how they work, and their various properties, read this Cookies tutorial.

PROPERTY	DESCRIPTION
`cacheRolesInCookie`	A Boolean value that indicates whether cookie caching is used. Defaults to `false`.
`cookieName`	The name of the role cache cookie. The default value is ".ASPXROLES".
`cookiePath`	The path for the roles name cookie. The path attribute enables a developer to limit the scope of a cookie to a particular directory hierarchy. The default value is "/", which informs the browser to send the authentication ticket cookie to any request made to the domain.
`cookieProtection`	Indicates what techniques are used to protect the role cache cookie. The allowable values are: `All` (the default); `Encryption`; `None`; and `Validation`. Refer back to Step 3 of the *Forms Authentication Configuration and Advanced Topics* tutorial for more information on these protection levels.
`cookieRequireSSL`	A Boolean value that indicates whether an SSL connection is required to transmit the authentication cookie. The default value is `false`.

PROPERTY	DESCRIPTION
`cookieSlidingExpiration`	A Boolean value that indicates whether the cookie's timeout is reset each time the user visits the site during a single session. The default value is `false`. This value is only pertinent when `createPersistentCookie` is set to `true`.
`cookieTimeout`	Specifies the time, in minutes, after which the authentication ticket cookie expires. The default value is `30`. This value is only pertinent when `createPersistentCookie` is set to `true`.
`createPersistentCookie`	A Boolean value that specifies whether the role cache cookie is a session cookie or persistent cookie. If `false` (the default), a session cookie is used, which is deleted when the browser is closed. If `true`, a persistent cookie is used; it expires `cookieTimeout` number of minutes after it has been created or after the previous visit, depending on the value of `cookieSlidingExpiration`.
`domain`	Specifies the cookie's domain value. The default value is an empty string, which causes the browser to use the domain from which it was issued (such as www.yourdomain.com). In this case, the cookie will **not** be sent when making requests to subdomains, such as admin.yourdomain.com. If you want the cookie to be passed to all subdomains you need to customize the `domain` attribute, setting it to "yourdomain.com".
`maxCachedResults`	Specifies the maximum number of role names that are cached in the cookie. The default is 25. The `RoleManagerModule` does not create a cookie for users that belong to more than `maxCachedResults` roles. Consequently, the `RolePrincipal` object's `IsInRole` method will use the `Roles` class to determine the user's roles. The reason `maxCachedResults` exists is because many user agents do not permit cookies larger than 4,096 bytes. So this cap is meant to reduce the likelihood of exceeding this size limitation. If you have extremely long role names, you may want to consider specifying a smaller `maxCachedResults` value; contrariwise, if you have extremely short role names, you can probably increase this value.

Table 1: The Role Cache Cookie Configuration Options

Let's configure our application to use non-persistent role cache cookies. To accomplish this, update the `<roleManager>` element in `Web.config` to include the following cookie-related attributes:

```
<roleManager enabled="true"
          defaultProvider="SecurityTutorialsSqlRoleProvider"
          cacheRolesInCookie="true"
          createPersistentCookie="false"
          cookieProtection="All">

     <providers>
     ...
     </providers>
</roleManager>
```

I updated the `<roleManager>` element by adding three attributes: `cacheRolesInCookie`, `createPersistentCookie`, and `cookieProtection`. By setting `cacheRolesInCookie` to `true`, the `RoleManagerModule` will now automatically cache the user's roles in a cookie rather than having to lookup the user's role information on each request. I explicitly set the `createPersistentCookie` and `cookieProtection` attributes to `false` and `All`, respectively. Technically, I didn't need to specify values for these attributes since I just assigned them to their default values, but I put them here to make it explicitly clear that I am not using persistent cookies and that the cookie is both encrypted and validated.

That's all there is to it! Henceforth, the Roles framework will cache the users' roles in cookies. If the user's browser does not support cookies, or if their cookies are deleted or lost, somehow, it's no big deal – the `RolePrincipal` object will simply use the `Roles` class in the case that no cookie (or an invalid or expired one) is available.

> **NOTE**
> Microsoft's Patterns & Practices group discourages using persistent role cache cookies. Since possession of the role cache cookie is sufficient to prove role membership, if a hacker can somehow gain access to a valid user's cookie he can impersonate that user. The likelihood of this happening increases if the cookie is persisted on the user's browser. For more information on this security recommendation, as well as other security concerns, refer to the Security Question List for ASP.NET 2.0.

Step 1: Defining Role-Based URL Authorization Rules

As discussed in the *User-Based Authorization* tutorial, URL authorization offers a means to restrict access to a set of pages on a user-by-user or role-by-role basis. The URL authorization rules are spelled out in `Web.config` using the `<authorization>` element with `<allow>` and `<deny>` child elements. In addition to the user-related authorization rules discussed in previous tutorials, each `<allow>` and `<deny>` child element can also include:

- A particular role
- A comma-delimited list of roles

For example, the URL authorization rules grant access to those users in the Administrators and Supervisors roles, but deny access to all others:

```
<authorization>

    <allow roles="Administrators, Supervisors" />
    <deny users="*" />
</authorization>
```

The `<allow>` element in the above markup states that the Administrators and Supervisors roles are allowed; the `<deny>` element instructs that *all* users are denied.

Let's configure our application so that the `ManageRoles.aspx`, `UsersAndRoles.aspx`, and `CreateUserWizardWithRoles.aspx` pages are only accessible to those users in the Administrators role, while the `RoleBasedAuthorization.aspx` page remains accessible to all visitors.

To accomplish this, start by adding a `Web.config` file to the `Roles` folder.

Figure 3: Add a `Web.config` File to the `Roles` directory (Click to view full-size image)

Next, add the following configuration markup to `Web.config`:

```
<?xml version="1.0"?>

<configuration>
     <system.web>
          <authorization>
               <allow roles="Administrators" />
               <deny users="*"/>
          </authorization>

     </system.web>

     <!-- Allow all users to visit RoleBasedAuthorization.aspx -->
     <location path="RoleBasedAuthorization.aspx">
          <system.web>
               <authorization>
                    <allow users="*" />

               </authorization>
          </system.web>
     </location>
</configuration>
```

The `<authorization>` element in the `<system.web>` section indicates that only users in the Administrators role may access the ASP.NET resources in the `Roles` directory. The `<location>` element defines an alternate set of URL authorization rules for the `RoleBasedAuthorization.aspx` page, allowing all users to visit the page.

After saving your changes to `Web.config`, log in as a user that is not in the Administrators role and then try to visit one of the protected pages. The `UrlAuthorizationModule` will detect that you do not have permission to visit the requested resource; consequently, the `FormsAuthenticationModule` will redirect you to the login page. The login page will then redirect you to the `UnauthorizedAccess.aspx` page (see Figure 4). This final redirect from the login page to `UnauthorizedAccess.aspx` occurs because of code we added to the login page in Step 2 of the *User-Based Authorization* tutorial. In particular, the login page automatically redirects any authenticated user to `UnauthorizedAccess.aspx` if the querystring contains a `ReturnUrl` parameter, as this parameter indicates that the user arrived at the login page after attempting to view a page he was not authorized to view.

Figure 4: Only Users in the Administrators Role Can View the Protected Pages (Click to view full-size image)

Log off and then log in as a user that is in the Administrators role. Now you should be able to view the three protected pages.

Figure 5: Tito Can Visit the `UsersAndRoles.aspx` Page Because He is in the Administrators Role (Click to view full-size image)

NOTE

When specifying URL authorization rules – for roles or users – it is important to keep in mind that the rules are analyzed one at a time, from the top down. As soon as a match is found, the user is granted or denied access, depending on if the match was found in an `<allow>` or `<deny>` element. **If no match is found, the user is granted access.** Consequently, if you want to restrict access to one or more user accounts, it is imperative that you use a `<deny>` element as the last element in the URL authorization configuration. **If your URL authorization rules do not include a `<deny>` element, all users will be granted access.** For a more thorough discussion on how the URL authorization rules are analyzed, refer back to the "A Look at How the `UrlAuthorizationModule` Uses the Authorization Rules to Grant or Deny Access" section of the *User-Based Authorization* tutorial.

Step 2: Limiting Functionality Based On the Currently Logged In User's Roles

URL authorization makes it easy to specify coarse authorization rules that state what identities are permitted and which ones are denied from viewing a particular page (or all pages in a folder and its subfolders). However, in certain cases we may want to allow all users to visit a page, but limit the page's functionality based on the visiting user's roles. This may entail showing or hiding data based on the user's role, or offering additional functionality to users that belong to a particular role.

Such fine grain role-based authorization rules can be implemented either declaratively or programmatically (or through some combination of the two). In the next section we will see how to implement declarative fine grain authorization via the LoginView control. Following that, we will explore programmatic techniques. Before we can look at applying fine grain authorization rules, however, we first need to create a page whose functionality depends on the role of the user visiting it.

Let's create a page that lists all of the user accounts in the system in a GridView. The GridView will include each user's username, email address, last login date, and comments about the user. In addition to displaying each user's information, the GridView will include edit and delete capabilities. We will initially create this page with the edit and delete functionality available to all users. In the "Using the LoginView Control" and "Programmatically Limiting Functionality" sections we will see how to enable or disable these features based on the visiting user's role.

NOTE

The ASP.NET page we are about to build uses a GridView control to display the user accounts. Since this tutorial series focuses on forms authentication, authorization, user accounts, and roles, I do not want to spend too much time discussing the inner workings of the GridView control. While this tutorial provides specific step-by-step instructions for setting up this page, it does not delve into the details of why certain choices were made, or what effect particular properties have on the rendered output. For a thorough examination of the GridView control, check out my *Working with Data in ASP.NET 2.0* tutorial series.

Start by opening the `RoleBasedAuthorization.aspx` page in the `Roles` folder. Drag a GridView from the page onto the Designer and set its `ID` to `UserGrid`. In a moment we will write code that calls the `Membership`. `GetAllUsers` method and binds the resulting `MembershipUserCollection` object to the GridView. The `MembershipUserCollection` contains a `MembershipUser` object for each user account in the system; `MembershipUser` objects have properties like `UserName`, `Email`, `LastLoginDate` and so forth.

Before we write the code that binds the user accounts to the grid, let's first define the GridView's fields. From the GridView's Smart Tag, click the "Edit Columns" link to launch the Fields dialog box (see Figure 6). From here, uncheck the "Auto-generate fields" checkbox in the lower left corner. Since we want this GridView to include editing and deleting capabilities, add a CommandField and set its `ShowEditButton` and `ShowDeleteButton`

properties to True. Next, add four fields for displaying the `UserName`, `Email`, `LastLoginDate`, and `Comment` properties. Use a BoundField for the two read-only properties (`UserName` and `LastLoginDate`) and TemplateFields for the two editable fields (`Email` and `Comment`).

Have the first BoundField display the `UserName` property; set its `HeaderText` and `DataField` properties to "UserName". This field will not be editable, so set its `ReadOnly` property to True. Configure the `LastLoginDate` BoundField by setting its `HeaderText` to "Last Login" and its `DataField` to "LastLoginDate". Let's format the output of this BoundField so that just the date is displayed (instead of the date and time). To accomplish this, set this BoundField's `HtmlEncode` property to False and its `DataFormatString` property to "{0:d}". Also set the `ReadOnly` property to True.

Set the `HeaderText` properties of the two TemplateFields to "Email" and "Comment".

Figure 6: The GridView's Fields Can Be Configured Through the Fields Dialog Box (Click to view full-size image)

We now need to define the `ItemTemplate` and `EditItemTemplate` for the "Email" and "Comment" TemplateFields. Add a Label Web control to each of the `ItemTemplates` and bind their `Text` properties to the `Email` and `Comment` properties, respectively.

For the "Email" TemplateField, add a TextBox named `Email` to its `EditItemTemplate` and bind its `Text` property to the `Email` property using two-way databinding. Add a RequiredFieldValidator and RegularExpressionValidator to the `EditItemTemplate` to ensure that a visitor editing the Email property has entered a valid email address. For the "Comment" TemplateField, add a multi-line TextBox named `Comment` to its `EditItemTemplate`. Set the TextBox's `Columns` and `Rows` properties to 40 and 4, respectively, and then bind its `Text` property to the `Comment` property using two-way databinding.

After configuring these TemplateFields, their declarative markup should look similar to the following:

```
<asp:TemplateField HeaderText="Email">
     <ItemTemplate>
          <asp:Label runat="server" ID="Label1" Text='<%# Eval("Email")%>'></asp:Label>

     </ItemTemplate>
     <EditItemTemplate>
          <asp:TextBox runat="server" ID="Email" Text='<%# Bind("Email")%>'></asp:TextBox>

          <asp:RequiredFieldValidator ID="RequiredFieldValidator1" runat="server"
               ControlToValidate="Email" Display="Dynamic"
               ErrorMessage="You must provide an email address."
               SetFocusOnError="True">*</asp:RequiredFieldValidator>

          <asp:RegularExpressionValidator ID="RegularExpressionValidator1" runat="server"
               ControlToValidate="Email" Display="Dynamic"
               ErrorMessage="The email address you have entered is not valid. Please fix
               this and try again."
               SetFocusOnError="True"

               ValidationExpression="\w+([-+.']\w+)*@\w+([-.]\w+)*\.\w+([-.]\w+)*">*
          </asp:RegularExpressionValidator>
     </EditItemTemplate>
</asp:TemplateField>

<asp:TemplateField HeaderText="Comment">
     <ItemTemplate>
          <asp:Label runat="server" ID="Label2" Text='<%# Eval("Comment")%>'></asp:Label>

     </ItemTemplate>
     <EditItemTemplate>
          <asp:TextBox runat="server" ID="Comment" TextMode="MultiLine"
               Columns="40" Rows="4" Text='<%# Bind("Comment")%>'>

          </asp:TextBox>
     </EditItemTemplate>
</asp:TemplateField>
```

When editing or deleting a user account we will need to know that user's `UserName` property value. Set the GridView's `DataKeyNames` property to "UserName" so that this information is available through the GridView's `DataKeys` collection.

Finally, add a ValidationSummary control to the page and set its `ShowMessageBox` property to True and its `ShowSummary` property to False. With these settings, the ValidationSummary will display a client-side alert if the user attempts to edit a user account with a missing or invalid email address.

```
<asp:ValidationSummary ID="ValidationSummary1"
               runat="server"
               ShowMessageBox="True"
               ShowSummary="False" />
```

We have now completed this page's declarative markup. Our next task is to bind the set of user accounts to the GridView. Add a method named `BindUserGrid` to the `RoleBasedAuthorization.aspx` page's code-behind class that binds the `MembershipUserCollection` returned by `Membership.GetAllUsers` to the `UserGrid` GridView. Call this method from the `Page_Load` event handler on the first page visit.

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
     If Not Page.IsPostBack Then
          BindUserGrid()
     End If
End Sub

Private Sub BindUserGrid()
     Dim allUsers As MembershipUserCollection = Membership.GetAllUsers()
     UserGrid.DataSource = allUsers
     UserGrid.DataBind()
End Sub
```

With this code in place, visit the page through a browser. As Figure 7 shows, you should see a GridView listing information about each user account in the system.

Figure 7: The `UserGrid` GridView Lists Information About Each User in the System (Click to view full-size image)

> **NOTE**
>
> The `UserGrid` GridView lists all of the users in a non-paged interface. This simple grid interface is not suitable for scenarios where there are several dozen or more users. One option is to configure the GridView to enable paging. The `Membership.GetAllUsers` method has two overloads: one that accepts no input parameters and returns all of the users and one that takes in integer values for the page index and page size, and returns only the specified subset of the users. The second overload can be used to more efficiently page through the users since it returns just the precise subset of user accounts rather than *all* of them. If you have thousands of user accounts, you might want to consider a filter-based interface, one that only shows those users whose UserName begins with a selected character, for instance. The `Membership.FindUsersByName` method is ideal for building a filter-based user interface. We will look at building such an interface in a future tutorial.

The GridView control offers built-in editing and deleting support when the control is bound to a properly configured data source control, such as the SqlDataSource or ObjectDataSource. The `UserGrid` GridView, however, has its data programmatically bound; therefore, we must write code to perform these two tasks. In particular, we will need to create event handlers for the GridView's `RowEditing`, `RowCancelingEdit`, `RowUpdating`, and `RowDeleting` events, which are fired when a visitor clicks the GridView's Edit, Cancel, Update, or Delete buttons.

Start by creating the event handlers for the GridView's `RowEditing`, `RowCancelingEdit`, and `RowUpdating` events and then add the following code:

```
Protected Sub UserGrid_RowEditing(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewEditEventArgs) Handles UserGrid.RowEditing
     ' Set the grid's EditIndex and rebind the data

     UserGrid.EditIndex = e.NewEditIndex
     BindUserGrid()
End Sub

Protected Sub UserGrid_RowCancelingEdit(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewCancelEditEventArgs) Handles UserGrid.RowCancelingEdit
     ' Revert the grid's EditIndex to -1 and rebind the data
     UserGrid.EditIndex = -1
     BindUserGrid()
End Sub

Protected Sub UserGrid_RowUpdating(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewUpdateEventArgs) Handles UserGrid.RowUpdating
     ' Exit if the page is not valid
     If Not Page.IsValid Then
          Exit Sub
     End If

     ' Determine the username of the user we are editing
     Dim UserName As String = UserGrid.DataKeys(e.RowIndex).Value.ToString()

     ' Read in the entered information and update the user
     Dim EmailTextBox As TextBox = CType(UserGrid.Rows(e.RowIndex).FindControl("Email"),TextBox)
     Dim CommentTextBox As TextBox= CType(UserGrid.Rows(e.RowIndex).FindControl("Comment"),TextBox)

     ' Return information about the user
     Dim UserInfo As MembershipUser = Membership.GetUser(UserName)

     ' Update the User account information
     UserInfo.Email = EmailTextBox.Text.Trim()
     UserInfo.Comment = CommentTextBox.Text.Trim()

     Membership.UpdateUser(UserInfo)

     ' Revert the grid's EditIndex to -1 and rebind the data
     UserGrid.EditIndex = -1
     BindUserGrid()
End Sub
```

The `RowEditing` and `RowCancelingEdit` event handlers simply set the GridView's `EditIndex` property and then rebind the list of user accounts to the grid. The interesting stuff happens in the `RowUpdating` event handler. This event handler starts by ensuring that the data is valid and then grabs the `UserName` value of the edited user account from the `DataKeys` collection. The `Email` and `Comment` TextBoxes in the two TemplateFields' `EditItemTemplate` s are then programmatically referenced. Their `Text` properties contain the edited email address and comment.

In order to update a user account through the Membership API we need to first get the user's information, which we do via a call to `Membership.GetUser(userName)`. The returned `MembershipUser` object's `Email` and `Comment` properties are then updated with the values entered into the two TextBoxes from the editing interface. Finally, these modifications are saved with a call to `Membership.UpdateUser`. The `RowUpdating` event handler completes by reverting the GridView to its pre-editing interface.

Next, create the `RowDeleting` RowDeleting event handler and then add the following code:

```
Protected Sub UserGrid_RowDeleting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs) Handles UserGrid.RowDeleting

     ' Determine the username of the user we are editing
     Dim UserName As String = UserGrid.DataKeys(e.RowIndex).Value.ToString()

     ' Delete the user
     Membership.DeleteUser(UserName)

     ' Revert the grid's EditIndex to -1 and rebind the data
     UserGrid.EditIndex = -1
     BindUserGrid()
End Sub
```

The above event handler starts by grabbing the `UserName` value from the GridView's `DataKeys` collection; this `UserName` value is then passed into the Membership class's `DeleteUser` method. The `DeleteUser` method deletes the user account from the system, including related membership data (such as what roles this user belongs to). After deleting the user, the grid's `EditIndex` is set to -1 (in case the user clicked Delete while another row was in edit mode) and the `BindUserGrid` method is called.

> **NOTE**
>
> The Delete button does not require any sort of confirmation from the user before deleting the user account. I encourage you to add some form of user confirmation to lessen the chance of an account being accidentally deleted. One of the easiest ways to confirm an action is through a client-side confirm dialog box. For more information on this technique, see Adding Client-Side Confirmation When Deleting.

Verify that this page functions as expected. You should be able to edit any user's email address and comment, as well as delete any user account. Since the `RoleBasedAuthorization.aspx` page is accessible to all users, any user – even anonymous visitors – can visit this page and edit and delete user accounts! Let's update this page so that only users in the Supervisors and Administrators roles can edit a user's email address and comment, and only Administrators can delete a user account.

The "Using the LoginView Control" section looks at using the LoginView control to show instructions specific to the user's role. If a person in the Administrators role visits this page, we will show instructions on how to edit and delete users. If a user in the Supervisors role reaches this page, we will show instructions on editing users. And if the visitor is anonymous or is not in either the Supervisors or Administrators role, we will display a message explaining that they cannot edit or delete user account information. In the "Programmatically Limiting Functionality" section we will write code that programmatically shows or hides the Edit and Delete buttons based on the user's role.

Using the LoginView Control

As we've seen in past tutorials, the LoginView control is useful for displaying different interfaces for authenticated and anonymous users, but the LoginView control can also be used to display different markup based on the user's roles. Let's use a LoginView control to display different instructions based on the visiting user's role.

Start by adding a LoginView above the `UserGrid` GridView. As we've discussed earlier, the LoginView control has two built-in templates: `AnonymousTemplate` and `LoggedInTemplate`. Enter a brief message in both of these templates that informs the user that they cannot edit or delete any user information.

```
<asp:LoginView ID="LoginView1" runat="server">
     <LoggedInTemplate>
          You are not a member of the Supervisors or Administrators roles. Therefore you
           cannot edit or delete any user information.
     </LoggedInTemplate>
     <AnonymousTemplate>

          You are not logged into the system. Therefore you cannot edit or delete any user
           information.
     </AnonymousTemplate>
</asp:LoginView>
```

In addition to the `AnonymousTemplate` and `LoggedInTemplate`, the LoginView control can include *RoleGroups*, which are role-specific templates. Each RoleGroup contains a single property, `Roles`, which specifies what roles the RoleGroup applies to. The `Roles` property can be set to a single role (like "Administrators") or to a comma-delimited list of roles (like "Administrators, Supervisors").

To manage the RoleGroups, click the "Edit RoleGroups" link from the control's Smart Tag to bring up the RoleGroup Collection Editor. Add two new RoleGroups. Set the first RoleGroup's `Roles` property to "Administrators" and the second's to "Supervisors".

Figure 8: Manage the LoginView's Role-Specific Templates Through the RoleGroup Collection Editor (Click to view full-size image)

Click OK to close the RoleGroup Collection Editor; this updates the LoginView's declarative markup to include a `<RoleGroups>` section with an `<asp:RoleGroup>` child element for each RoleGroup defined in the RoleGroup Collection Editor. Furthermore, the "Views" drop-down list in the LoginView's Smart Tag - which initially listed just the `AnonymousTemplate` and `LoggedInTemplate` – now includes the added RoleGroups as well.

Edit the RoleGroups so that users in the Supervisors role are displayed instructions on how to edit user accounts, while users in the Administrators role are shown instructions for editing and deleting. After making these changes, your LoginView's declarative markup should look similar to the following.

```
<asp:LoginView ID="LoginView1" runat="server">
     <RoleGroups>
          <asp:RoleGroup Roles="Administrators">

               <ContentTemplate>
                    As an Administrator, you may edit and delete user accounts.
                    Remember: With great power comes great responsibility!
               </ContentTemplate>
          </asp:RoleGroup>
          <asp:RoleGroup Roles="Supervisors">
               <ContentTemplate>
                    As a Supervisor, you may edit users&#39; Email and Comment information.
                    Simply click the Edit button, make your changes, and then click Update.
               </ContentTemplate>

          </asp:RoleGroup>
     </RoleGroups>
     <LoggedInTemplate>
          You are not a member of the Supervisors or Administrators roles.
          Therefore you cannot edit or delete any user information.
     </LoggedInTemplate>
     </AnonymousTemplate>
          You are not logged into the system.
          Therefore you cannot edit or delete any user information.
     </AnonymousTemplate>
</asp:LoginView>
```

After making these changes, save the page and then visit it through a browser. First visit the page as an anonymous user. You should be shown the message, "You are not logged into the system. Therefore you cannot edit or delete any user information." Then log in as an authenticated user, but one that is neither in the Supervisors nor Administrators role. This time you should see the message, "You are not a member of the Supervisors or Administrators roles. Therefore you cannot edit or delete any user information."

Next, log in as a user who is a member of the Supervisors role. This time you should see the Supervisors role-specific message (see Figure 9). And if you log in as a user in the Administrators role you should see the Administrators role-specific message (see Figure 10).

Figure 9: Bruce is Shown the Supervisors Role-Specific Message (Click to view full-size image)

Figure 10: Tito is Shown the Administrators Role-Specific Message (Click to view full-size image)

As the screen shots in Figures 9 and 10 show, the LoginView only renders one template, even if multiple templates apply. Bruce and Tito are both logged in users, yet the LoginView renders only the matching RoleGroup and not the `LoggedInTemplate`. Moreover, Tito belongs to both the Administrators and Supervisors roles, yet the LoginView control renders the Administrators role-specific template instead of the Supervisors one.

Figure 11 illustrates the workflow used by the LoginView control to determine what template to render. Note that if there is more than one RoleGroup specified, the LoginView template renders the *first* RoleGroup that matches. In other words, if we had placed the Supervisors RoleGroup as the first RoleGroup and the Administrators as the second, then when Tito visited this page he would see the Supervisors message.

Figure 11: The LoginView Control's Workflow for Determining What Template to Render (Click to view full-size image)

Programmatically Limiting Functionality

While the LoginView control displays different instructions based on the role of the user visiting the page, the Edit and Cancel buttons remain visible to all. We need to programmatically hide the Edit and Delete buttons for

anonymous visitors and users who are in neither the Supervisors nor Administrators role. We need to hide the Delete button for everyone who is not an Administrator. In order to accomplish this we will write a bit of code that programmatically references the CommandField's Edit and Delete LinkButtons and sets their `Visible` properties to `False`, if necessary.

The easiest way to programmatically reference controls in a CommandField is to first convert it to a template. To accomplish this, click the "Edit Columns" link from the GridView's Smart Tag, select the CommandField from the list of current fields, and click the "Convert this field into a TemplateField" link. This turns the CommandField into a TemplateField with an `ItemTemplate` and `EditItemTemplate`. The `ItemTemplate` contains the Edit and Delete LinkButtons while the `EditItemTemplate` houses the Update and Cancel LinkButtons.

Figure 12: Convert the CommandField Into a TemplateField (Click to view full-size image)

Update the Edit and Delete LinkButtons in the `ItemTemplate`, setting their `ID` properties to values of `EditButton` and `DeleteButton`, respectively.

```
<asp:TemplateField ShowHeader="False">
     <EditItemTemplate>
          <asp:LinkButton ID="LinkButton1" runat="server" CausesValidation="True"
               CommandName="Update" Text="Update"></asp:LinkButton>

           <asp:LinkButton ID="LinkButton2" runat="server" CausesValidation="False"
               CommandName="Cancel" Text="Cancel"></asp:LinkButton>

     </EditItemTemplate>
     <ItemTemplate>
          <asp:LinkButton ID="EditButton" runat="server" CausesValidation="False"
               CommandName="Edit" Text="Edit"></asp:LinkButton>

           <asp:LinkButton ID="DeleteButton" runat="server" CausesValidation="False"
               CommandName="Delete" Text="Delete"></asp:LinkButton>

     </ItemTemplate>
</asp:TemplateField>
```

Whenever data is bound to the GridView, the GridView enumerates the records in its `DataSource` property and generates a corresponding `GridViewRow` object. As each `GridViewRow` object is created, the `RowCreated` event is fired. In order to hide the Edit and Delete buttons for unauthorized users, we need to create an event handler for this event and programmatically reference the Edit and Delete LinkButtons, setting their `Visible` properties

accordingly.

Create an event handler the `RowCreated` event and then add the following code:

```
Protected Sub UserGrid_RowCreated(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewRowEventArgs) Handles UserGrid.RowCreated
     If e.Row.RowType = DataControlRowType.DataRow AndAlso e.Row.RowIndex <> UserGrid.EditIndex Then
          ' Programmatically reference the Edit and Delete LinkButtons
          Dim EditButton As LinkButton = CType(e.Row.FindControl("EditButton"), LinkButton)

          Dim DeleteButton As LinkButton = CType(e.Row.FindControl("DeleteButton"), LinkButton)

          EditButton.Visible = (User.IsInRole("Administrators") OrElse User.IsInRole("Supervisors"))
          DeleteButton.Visible = User.IsInRole("Administrators")
     End If
End Sub
```

Keep in mind that the `RowCreated` event fires for *all* of the GridView rows, including the header, the footer, the pager interface, and so forth. We only want to programmatically reference the Edit and Delete LinkButtons if we are dealing with a data row not in edit mode (since the row in edit mode has Update and Cancel buttons instead of Edit and Delete). This check is handled by the `If` statement.

If we are dealing with a data row that is not in edit mode, the Edit and Delete LinkButtons are referenced and their `Visible` properties are set based on the Boolean values returned by the `User` object's `IsInRole(roleName)` method. The `User` object references the principal created by the `RoleManagerModule`; consequently, the `IsInRole(roleName)` method uses the Roles API to determine whether the current visitor belongs to *roleName*.

> **NOTE**
>
> We could have used the Roles class directly, replacing the call to `User.IsInRole(roleName)` with a call to the `Roles.IsUserInRole(roleName)` method. I decided to use the principal object's `IsInRole(roleName)` method in this example because it is more efficient than using the Roles API directly. Earlier in this tutorial we configured the role manager to cache the user's roles in a cookie. This cached cookie data is only utilized when the principal's `IsInRole(roleName)` method is called; direct calls to the Roles API always involve a trip to the role store. Even if roles are not cached in a cookie, calling the principal object's `IsInRole(roleName)` method is usually more efficient because when it is called for the first time during a request it caches the results. The Roles API, on the other hand, does not perform any caching. Because the `RowCreated` event is fired once for every row in the GridView, using `User.IsInRole(roleName)` involves just one trip to the role store whereas `Roles.IsUserInRole(roleName)` requires *N* trips, where *N* is the number of user accounts displayed in the grid.

The Edit button's `Visible` property is set to `True` if the user visiting this page is in the Administrators or Supervisors role; otherwise it is set to `False`. The Delete button's `Visible` property is set to `True` only if the user is in the Administrators role.

Test this page through a browser. If you visit the page as an anonymous visitor or as a user that is neither a Supervisor nor an Administrator, the CommandField is empty; it still exists, but as a thin sliver without the Edit or Delete buttons.

> **NOTE**
>
> It is possible to hide the CommandField altogether when a non-Supervisor and non-Administrator is visiting the page. I leave this as an exercise for the reader.

Figure 13: The Edit and Delete Buttons are Hidden for Non-Supervisors and Non-Administrators (Click to view full-size image)

If a user that belongs to the Supervisors role (but not to the Administrators role) visits, he sees only the Edit button.

Figure 14: While the Edit Button is Available for Supervisors, the Delete Button is Hidden (Click to view full-size image)

And if an Administrator visits, she has access to both the Edit and Delete buttons.

Figure 15: The Edit and Delete Buttons are Available Only for Administrators (Click to view full-size image)

Step 3: Applying Role-Based Authorization Rules to Classes and Methods

In Step 2 we limited edit capabilities to users in the Supervisors and Administrators roles and delete capabilities to Administrators only. This was accomplished by hiding the associated user interface elements for unauthorized users through programmatic techniques. Such measures do not guarantee that an unauthorized user will be unable to perform a privileged action. There may be user interface elements that are added later or that we forgot to hide for unauthorized users. Or a hacker may discover some other way to get the ASP.NET page to execute the desired method.

An easy way to ensure that a particular piece of functionality cannot be accessed by an unauthorized user is to decorate that class or method with the `PrincipalPermission` attribute. When the .NET runtime uses a class or executes one of its methods, it checks to ensure that the current security context has permission. The `PrincipalPermission` attribute provides a mechanism through which we can define these rules.

We looked at using the `PrincipalPermission` attribute back in the *User-Based Authorization* tutorial. Specifically, we saw how to decorate the GridView's `SelectedIndexChanged` and `RowDeleting` event handler so that they could only be executed by authenticated users and Tito, respectively. The `PrincipalPermission` attribute works just as well with roles.

Let's demonstrate using the `PrincipalPermission` attribute on the GridView's `RowUpdating` and `RowDeleting` event handlers to prohibit execution for non-authorized users. All we need to do is add the appropriate attribute atop each function definition:

```
<PrincipalPermission(SecurityAction.Demand, Role:="Administrators")>_
<PrincipalPermission(SecurityAction.Demand, Role:="Supervisors")>_
Protected Sub UserGrid_RowUpdating(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewUpdateEventArgs) Handles UserGrid.RowUpdating
     ...
End Sub

<PrincipalPermission(SecurityAction.Demand, Role:="Administrators")>_
Protected Sub UserGrid_RowDeleting(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.GridViewDeleteEventArgs) Handles UserGrid.RowDeleting
     ...
End Sub
```

The attribute for the `RowUpdating` event handler dictates that only users in the Administrators or Supervisors

roles can execute the event handler, where as the attribute on the `RowDeleting` event handler limits the execution to users in the Administrators role.

> **NOTE**
> The `PrincipalPermission` attribute is represented as a class in the `System.Security.Permissions` namespace. Be sure to add a `Imports System.Security.Permissions` statement at the top of your code-behind class file to import this namespace.

If, somehow, a non-Administrator attempts to execute the `RowDeleting` event handler or if a non-Supervisor or non-Administrator attempts to execute the `RowUpdating` event handler, the .NET runtime will raise a `SecurityException`.

Figure 16: If the Security Context is not Authorized to Execute the Method, a `SecurityException` is Thrown (Click to view full-size image)

In addition to ASP.NET pages, many applications also have an architecture that includes various layers, such as Business Logic and Data Access Layers. These layers are typically implemented as Class Libraries and offer classes and methods for performing business logic- and data-related functionality. The `PrincipalPermission` attribute is useful for applying authorization rules to these layers as well.

For more information on using the `PrincipalPermission` attribute to define authorization rules on classes and methods, refer to Scott Guthrie's blog entry Adding Authorization Rules to Business and Data Layers Using `PrincipalPermissionAttributes`.

Summary

In this tutorial we looked at how to specify coarse and fine grain authorization rules based on the user's roles. ASP.NET's URL authorization feature allows a page developer to specify what identities are allowed or denied access to what pages. As we saw back in the *User-Based Authorization* tutorial, URL authorization rules can be applied on a user-by-user basis. They can also be applied on a role-by-role basis, as we saw in Step 1 of this tutorial.

Fine grain authorization rules may be applied declaratively or programmatically. In Step 2 we looked at using the LoginView control's RoleGroups feature to render different output based on the visiting user's roles. We also looked at ways to programmatically determine if a user belongs to a specific role and how to adjust the page's functionality accordingly.

Happy Programming!

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will build a user interface with a paged, filterable grid. In particular, our user interface will consist of a series of LinkButtons for filtering the results based on the starting letter of the username, and a GridView control to show the matching users. We'll start by listing all of the user accounts in a GridView. Then, in Step 3, we will add the filter LinkButtons. Step 4 looks at paging the filtered results. The interface constructed in Steps 2 through 4 will be used in the subsequent tutorials to perform administrative tasks for a particular user account.

Introduction

In the *Assigning Roles to Users* tutorial, we created a rudimentary interface for an administrator to select a user and manage her roles. Specifically, the interface presented the administrator with a drop-down list of all of the users. Such an interface is suitable when there are but a dozen or so user accounts, but is unwieldy for sites with hundreds or thousands of accounts. A paged, filterable grid is more suitable user interface for websites with large user bases.

In this tutorial we will build such a user interface. In particular, our user interface will consist of a series of LinkButtons for filtering the results based on the starting letter of the username, and a GridView control to show the matching users. We'll start by listing all of the user accounts in a GridView. Then, in Step 3, we will add the filter LinkButtons. Step 4 looks at paging the filtered results. The interface constructed in Steps 2 through 4 will be used in the subsequent tutorials to perform administrative tasks for a particular user account.

Let's get started!

Step 1: Adding New ASP.NET Pages

In this tutorial and the next two we will be examining various administration-related functions and capabilities. We will need a series of ASP.NET pages to implement the topics examined throughout these tutorials. Let's create these pages and update the site map.

Start by creating a new folder in the project named `Administration`. Next, add two new ASP.NET pages to the folder, linking each page with the `Site.master` master page. Name the pages:

- `ManageUsers.aspx`
- `UserInformation.aspx`

Also add two pages to the website's root directory: `ChangePassword.aspx` and `RecoverPassword.aspx`.

These four pages should, at this point, have two Content controls, one for each of the master page's ContentPlaceHolders: `MainContent` and `LoginContent`.

```
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="LoginContent" Runat="Server">
</asp:Content>
```

We want to show the master page's default markup for the `LoginContent` ContentPlaceHolder for these pages. Therefore, remove the declarative markup for the `Content2` Content control. After doing so, the pages' markup should contain just one Content control.

The ASP.NET pages in the `Administration` folder are intended solely for administrative users. We added an Administrators role to the system in the *Creating and Managing Roles* tutorial; restrict access to these two pages to this role. To accomplish this, add a `Web.config` file to the `Administration` folder and configure its `<authorization>` element to admit users in the Administrators role and to deny all others.

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 <authorization>
 <allow roles="Administrators" />
 <deny users="*"/>
 </authorization>
 </system.web>
</configuration>
```

At this point your project's Solution Explorer should look similar to the screen shot shown in Figure 1.

Figure 1: Four New Pages and a `Web.config` File Have Been Added to the Website (Click to view full-size image)

Finally, update the site map (`Web.sitemap`) to include an entry to the `ManageUsers.aspx` page. Add the following XML after the `<siteMapNode>` we added for the Roles tutorials.

```
<siteMapNode title="User Administration" url="~/Administration/ManageUsers.aspx"/>
```

With the site map updated, visit the site through a browser. As Figure 2 shows, the navigation on the left now includes items for the Administration tutorials.

Figure 2: The Site Map Includes a Node Titled User Administration (Click to view full-size image)

Step 2: Listing All User Accounts in a GridView

Our end goal for this tutorial is to create a paged, filterable grid through which an administrator can select a user account to manage. Let's start by listing *all* users in a GridView. Once this is complete, we will add the filtering and paging interfaces and functionality.

Open the `ManageUsers.aspx` page in the `Administration` folder and add a GridView, setting its `ID` to `UserAccounts`. In a moment, we will write code to bind the set of user accounts to the GridView using the `Membership` class's `GetAllUsers` method. As discussed in earlier tutorials, the GetAllUsers method returns a `MembershipUserCollection` object, which is a collection of `MembershipUser` objects. Each `MembershipUser` in the collection includes properties like `UserName`, `Email`, `IsApproved`, and so on.

In order to display the desired user account information in the GridView, set the GridView's `AutoGenerateColumns` property to False and add BoundFields for the `UserName`, `Email`, and `Comment` properties and CheckBoxFields for the `IsApproved`, `IsLockedOut`, and `IsOnline` properties. This configuration can be applied through the control's declarative markup or via the Fields dialog box. Figure 3 shows a screen shot of the Fields dialog box after the Auto-generate fields checkbox has been unchecked and the BoundFields and CheckBoxFields have been added and configured.

Figure 3: Add Three BoundFields and Three CheckBoxFields to the GridView (Click to view full-size image)

After configuring your GridView, ensure that its declarative markup resembles the following:

```
<asp:GridView ID="UserAccounts" runat="server" AutoGenerateColumns="False">
 <Columns>
 <asp:BoundField DataField="UserName" HeaderText="UserName"/>
 <asp:BoundField DataField="Email" HeaderText="Email" />
 <asp:CheckBoxField DataField="IsApproved" HeaderText="Approved?"/>
 <asp:CheckBoxField DataField="IsLockedOut" HeaderText="Locked Out?" />
 <asp:CheckBoxField DataField="IsOnline" HeaderText="Online?"/>
 <asp:BoundField DataField="Comment" HeaderText="Comment"/>
 </Columns>
</asp:GridView>
```

Next, we need to write code that binds the user accounts to the GridView. Create a method named `BindUserAccounts` to perform this task and then call it from the `Page_Load` event handler on the first page visit.

```
protected void Page_Load(object sender, EventArgs e)
{
    if (!Page.IsPostBack)
    BindUserAccounts();
}

private void BindUserAccounts()
{
    UserAccounts.DataSource = Membership.GetAllUsers();
    UserAccounts.DataBind();
}
```

Take a moment to test the page through a browser. As Figure 4 shows, the `UserAccounts` GridView lists the username, email address, and other pertinent account information for all users in the system.

Figure 4: The User Accounts are Listed in the GridView (Click to view full-size image)

Step 3: Filtering the Results by the First Letter of the Username

Currently the `UserAccounts` GridView shows *all* of the user accounts. For websites with hundreds or thousands of user accounts, it is imperative that user be able to quickly pare down the displayed accounts. This can be accomplished by adding filtering LinkButtons to the page. Let's add 27 LinkButtons to the page: one titled All along with one LinkButton for each letter of the alphabet. If a visitor clicks the All LinkButton, the GridView will show all of the users. If they click a particular letter, only those users whose username starts with the selected letter will be displayed.

Our first task is to add the 27 LinkButton controls. One option would be to create the 27 LinkButtons declaratively, one at a time. A more flexible approach is to use a Repeater control with an `ItemTemplate` that renders a LinkButton and then binds the filtering options to the Repeater as a `string` array.

Start by adding a Repeater control to the page above the `UserAccounts` GridView. Set the Repeater's `ID` property to `FilteringUI`. Configure the Repeater's templates so that its `ItemTemplate` renders a LinkButton whose `Text` and `CommandName` properties are bound to the current array element. As we saw in the *Assigning Roles to Users* tutorial, this can be accomplished using the `Container.DataItem` databinding syntax. Use the Repeater's `SeparatorTemplate` to display a vertical line between each link.

```
<asp:Repeater ID="FilteringUI" runat="server">
 <ItemTemplate>
 <asp:LinkButton runat="server" ID="lnkFilter"
 Text='<%# Container.DataItem %>'
 CommandName='<%# Container.DataItem %>'></asp:LinkButton>
 </ItemTemplate>
 <SeparatorTemplate>|</SeparatorTemplate>
</asp:Repeater>
```

To populate this Repeater with the desired filtering options, create a method named `BindFilteringUI`. Be sure to call this method from the `Page_Load` event handler on the first page load.

```
protected void Page_Load(object sender, EventArgs e)
{
    if (!Page.IsPostBack)
    {
        BindUserAccounts();
        BindFilteringUI();
    }
}

private void BindFilteringUI()
{
    string[] filterOptions = { "All", "A", "B", "C","D", "E", "F", "G", "H", "I","J", "K", "L", "M", "N",
"O","P", "Q", "R", "S", "T", "U","V", "W", "X", "Y", "Z" };
    FilteringUI.DataSource = filterOptions;
    FilteringUI.DataBind();
}
```

This method specifies the filtering options as elements in the `string` array `filterOptions`. For each element in the array, the Repeater will render a LinkButton with its `Text` and `CommandName` properties assigned to the value of the array element.

Figure 5 shows the `ManageUsers.aspx` page when viewed through a browser.

Figure 5: The Repeater Lists 27 Filtering LinkButtons (Click to view full-size image)

> **NOTE**
>
> Usernames may start with any character, including numbers and punctuation. In order to view these accounts, the administrator will have to use the All LinkButton option. Alternatively, you could add a LinkButton to return all user accounts that start with a number. I leave this as an exercise for the reader.

Clicking any of the filtering LinkButtons causes a postback and raises the Repeater's `ItemCommand` event, but there's no change in the grid because we've yet to write any code to filter the results. The `Membership` class includes a `FindUsersByName` method that returns those user accounts whose username matches a specified search pattern. We can use this method to retrieve just those user accounts whose usernames start with the letter specified by the `CommandName` of the filtered LinkButton that was clicked.

Start by updating the `ManageUser.aspx` page's code-behind class so that it includes a property named `UsernameToMatch`. This property persists the username filter string across postbacks:

```
private string UsernameToMatch
{
 get
 {
 object o = ViewState["UsernameToMatch"];
 if (o == null)
 return string.Empty;
 else
 return (string)o;
 }
 set
 {
 ViewState["UsernameToMatch"] = value;
 }
}
```

The `UsernameToMatch` property stores its value it is assigned into the `ViewState` collection using the key UsernameToMatch. When this property's value is read, it checks to see if a value exists in the `ViewState` collection; if not, it returns the default value, an empty string. The `UsernameToMatch` property exhibits a common pattern, namely persisting a value to view state so that any changes to the property are persisted across postbacks. For more information on this pattern, read Understanding ASP.NET View State.

Next, update the `BindUserAccounts` method so that instead of calling `Membership.GetAllUsers`, it calls `Membership.FindUsersByName`, passing in the value of the `UsernameToMatch` property appended with the SQL wildcard character, %.

```
private void BindUserAccounts()
{
    UserAccounts.DataSource = Membership.FindUsersByName(this.UsernameToMatch + "%");
    UserAccounts.DataBind();
}
```

To display just those users whose username starts with the letter A, set the `UsernameToMatch` property to A and then call `BindUserAccounts`. This would result in a call to `Membership.FindUsersByName("A%")`, which will return all users whose username starts with A. Likewise, to return *all* users, assign an empty string to the `UsernameToMatch` property so that the `BindUserAccounts` method will invoke `Membership.FindUsersByName("%")`, thereby returning all user accounts.

Create an event handler for the Repeater's `ItemCommand` event. This event is raised whenever one of the filter LinkButtons is clicked; it is passed the clicked LinkButton's `CommandName` value through the `RepeaterCommandEventArgs` object. We need to assign the appropriate value to the `UsernameToMatch` property and then call the `BindUserAccounts` method. If the `CommandName` is All, assign an empty string to `UsernameToMatch` so that all user accounts are displayed. Otherwise, assign the `CommandName` value to `UsernameToMatch`.

```
protected void FilteringUI_ItemCommand(object source, RepeaterCommandEventArgs e)
{
    if (e.CommandName == "All")
        this.UsernameToMatch = string.Empty;
    else
        this.UsernameToMatch e.CommandName;
    BindUserAccounts();
}
```

With this code in place, test out the filtering functionality. When the page is first visited, all user accounts are displayed (refer back to Figure 5). Clicking the A LinkButton causes a postback and filters the results, displaying only those user accounts that start with A .

Figure 6: Use the Filtering LinkButtons to Display those Users Whose Username Starts with a Certain Letter (Click to view full-size image)

Step 4: Updating the GridView to Use Paging

The GridView shown in Figures 5 and 6 lists all of the records returned from the `FindUsersByName` method. If there are hundreds or thousands of user accounts this can lead to information overload when viewing all of the accounts (as is the case when clicking the All LinkButton or when initially visiting the page). To help present the user accounts in more manageable chunks, let's configure the GridView to display 10 user accounts at a time.

The GridView control offers two types of paging:

- **Default paging** - easy to implement, but inefficient. In a nutshell, with default paging the GridView expects *all* of the records from its data source. It then only displays the appropriate page of records.
- **Custom paging** - requires more work to implement, but is more efficient than default paging because with custom paging the data source returns only the precise set of records to display.

The performance difference between default and custom paging can be quite substantial when paging through thousands of records. Because we are building this interface assuming that there may be hundreds or thousands of user accounts, let's use custom paging.

> **NOTE**
>
> For a more thorough discussion on the differences between default and custom paging, as well as the challenges involved in implementing custom paging, refer to Efficiently Paging Through Large Amounts of Data. For some analysis of the performance difference between default and custom paging, see Custom Paging in ASP.NET with SQL Server 2005.

To implement custom paging we first need some mechanism by which to retrieve the precise subset of records being displayed by the GridView. The good news is that the `Membership` class's `FindUsersByName` method has an overload that allows us to specify the page index and page size, and returns only those user accounts that fall within that range of records.

In particular, this overload has the following signature: `FindUsersByName(usernameToMatch, pageIndex, pageSize, totalRecords)`.

The *pageIndex* parameter specifies the page of user accounts to return; *pageSize* indicates how many records to display per page. The *totalRecords* parameter is an `out` parameter that returns the number of total user accounts in the user store.

> **NOTE**
>
> The data returned by `FindUsersByName` is sorted by username; the sort criteria cannot be customized.

The GridView can be configured to utilize custom paging, but only when bound to an ObjectDataSource control.

For the ObjectDataSource control to implement custom paging, it requires two methods: one that is passed a start row index and the maximum number of records to display, and returns the precise subset of records that fall within that span; and a method that returns the total number of records being paged through. The `FindUsersByName` overload accepts a page index and page size, and returns the total number of records through an `out` parameter. So there is an interface mismatch here.

One option would be to create a proxy class that exposes the interface the ObjectDataSource expects, and then internally calls the `FindUsersByName` method. Another option - and the one we'll use for this article - is to create our own paging interface and use that instead of the GridView's built-in paging interface.

Creating a First, Previous, Next, Last Paging Interface

Let's build a paging interface with First, Previous, Next, and Last LinkButtons. The First LinkButton, when clicked, will take the user to the first page of data, whereas Previous will return him to the previous page. Likewise, Next and Last will move the user to the next and last page, respectively. Add the four LinkButton controls beneath the `UserAccounts` GridView.

```
<p>
 <asp:LinkButton ID="lnkFirst" runat="server"> First</asp:LinkButton> |
 <asp:LinkButton ID="lnkPrev" runat="server">  Prev</asp:LinkButton>|
 <asp:LinkButton ID="lnkNext" runat="server">Next  </asp:LinkButton>|
 <asp:LinkButton ID="lnkLast" runat="server">Last  </asp:LinkButton>
</p>
```

Next, create an event handler for each of the LinkButton's `Click` events.

Figure 7 shows the four LinkButtons when viewed through the Visual Web Developer Design view.

Figure 7: Add First, Previous, Next, and Last LinkButtons Beneath the GridView (Click to view full-size image)

Keeping Track of the Current Page Index

When a user first visits the `ManageUsers.aspx` page or clicks one of the filtering buttons, we want to display the first page of data in the GridView. When the user clicks one of the navigation LinkButtons, however, we need to update the page index. To maintain the page index and the number of records to display per page, add the following two properties to the page's code-behind class:

```
private int PageIndex
{
 get
 {
 object o = ViewState["PageIndex"];
 if (o == null)
 return 0;
 else
 return (int)o;
 }
 set
 {
 ViewState["PageIndex"] = value;
 }
}

private int PageSize
{
 get
 {
 return 10;
 }
}
```

Like the `UsernameToMatch` property, the `PageIndex` property persists its value to view state. The read-only `PageSize` property returns a hard-coded value, 10. I invite the interested reader to update this property to use the same pattern as `PageIndex`, and then to augment the `ManageUsers.aspx` page such that the person visiting the page can specify how many user accounts to display per page.

Retrieving Just the Current Page's Records, Updating the Page Index, and Enabling and Disabling the Paging Interface LinkButtons

With the paging interface in place and the `PageIndex` and `PageSize` properties added, we are ready to update the `BindUserAccounts` method so that it uses the appropriate `FindUsersByName` overload. Additionally, we need to have this method enable or disable the paging interface depending on what page is being displayed. When viewing the first page of data, the First and Previous links should be disabled; Next and Last should be disabled when viewing the last page.

Update the `BindUserAccounts` method with the following code:

```
private void BindUserAccounts()
{
 int totalRecords;
 UserAccounts.DataSource = Membership.FindUsersByName(this.UsernameToMatch + "%",this.PageIndex,
this.PageSize, out totalRecords);
 UserAccounts.DataBind();

 // Enable/disable the paging interface
 bool visitingFirstPage = (this.PageIndex == 0);
 lnkFirst.Enabled = !visitingFirstPage;
 lnkPrev.Enabled = !visitingFirstPage;

 int lastPageIndex = (totalRecords - 1) / this.PageSize;
 bool visitingLastPage = (this.PageIndex >= lastPageIndex);
 lnkNext.Enabled = !visitingLastPage;
 lnkLast.Enabled = !visitingLastPage;
}
```

Note that the total number of records being paged through is determined by the last parameter of the `FindUsersByName` method. This is an `out` parameter, so we need to first declare a variable to hold this value (`totalRecords`) and then prefix it with the `out` keyword.

After the specified page of user accounts are returned, the four LinkButtons are either enabled or disabled, depending on whether the first or last page of data is being viewed.

The last step is to write the code for the four LinkButtons' `Click` event handlers. These event handlers need to update the `PageIndex` property and then rebind the data to the GridView via a call to `BindUserAccounts`. The First, Previous, and Next event handlers are very simple. The `Click` event handler for the Last LinkButton, however, is a bit more complex because we need to determine how many records are being displayed in order to determine the last page index.

```
protected void lnkFirst_Click(object sender, EventArgs e)
{
 this.PageIndex = 0;
 BindUserAccounts();
}

protected void lnkPrev_Click(object sender, EventArgs e)
{
 this.PageIndex -= 1;
 BindUserAccounts();
}

protected void lnkNext_Click(object sender, EventArgs e)
{
 this.PageIndex += 1;
 BindUserAccounts();
}

protected void lnkLast_Click(object sender, EventArgs e)
{
 // Determine the total number of records
 int totalRecords;
 Membership.FindUsersByName(this.UsernameToMatch + "%", this.PageIndex,this.PageSize, out totalRecords);
 // Navigate to the last page index
 this.PageIndex = (totalRecords - 1) / this.PageSize;
 BindUserAccounts();
}
```

Figures 8 and 9 show the custom paging interface in action. Figure 8 shows the `ManageUsers.aspx` page when viewing the first page of data for all user accounts. Note that only 10 of the 13 accounts are displayed. Clicking the Next or Last link causes a postback, updates the `PageIndex` to 1, and binds the second page of user accounts to the grid (see Figure 9).

Figure 8: The First 10 User Accounts are Displayed (Click to view full-size image)

Figure 9: Clicking the Next Link Displays the Second Page of User Accounts (Click to view full-size image)

Summary

Administrators often need to select a user from the list of accounts. In previous tutorials we looked at using a drop-down list populated with the users, but this approach does not scale well. In this tutorial we explored a better alternative: a filterable interface whose results are displayed in a paged GridView. With this user interface, administrators can quickly and efficiently locate and select one user account among thousands.

Happy Programming!

Recovering and Changing Passwords (C#)

2/20/2020 • 20 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

ASP.NET includes two Web controls for assisting with recovering and changing passwords. The PasswordRecovery control enables a visitor to recover his lost password. The ChangePassword control allows the user to update his password. Like the other Login-related Web controls we've seen throughout this tutorial series, the PasswordRecovery and ChangePassword controls work with the Membership framework behind the scenes to reset or modify users' passwords.

Introduction

Between the websites for my bank, utility company, phone company, email accounts, and personalized web portals, I, like most people, have dozens of different passwords to remember. With so many credentials to memorize these days, it's not uncommon for people to forget their password. To account for this, websites that offer user accounts need to include a way for a user to recover his password. This process typically involves generating a new, random password and emailing it to the user's email address on file. After receiving their new password most users return to the site and change their password from the randomly generated one to a more memorable one.

ASP.NET includes two Web controls for assisting with recovering and changing passwords. The PasswordRecovery control enables a visitor to recover his lost password. The ChangePassword control allows the user to update his password. Like the other Login-related Web controls we've seen throughout this tutorial series, the PasswordRecovery and ChangePassword controls work with the Membership framework behind the scenes to reset or modify users' passwords.

In this tutorial we will examine using these two controls. We will also see how to programmatically change and reset a user's password via the `MembershipUser` class's `ChangePassword` and `ResetPassword` methods.

Step 1: Helping Users Recover Lost Passwords

All websites that support user accounts need to provide users with some mechanism for recovering their forgotten passwords. The good news is that implementing such functionality in ASP.NET is a breeze thanks to the PasswordRecovery Web control. The PasswordRecovery control renders an interface that prompts the user for their username and, if needed, the answer to their security question. It then emails the user their password.

> **NOTE**
>
> Because email messages are transmitted over the wire in plain-text there are security risks involved with sending a user's password via email.

The PasswordRecovery control consists of three views:

- **UserName** - prompts the visitor for their username. This is the initial view.
- **Question**- displays the user's username and security question as text, along with a TextBox for the user to enter the answer to his security question.
- **Success**- displays a message informing the user that his password has been emailed.

The views displayed and actions performed by the PasswordRecovery control depend upon the following Membership configuration settings:

- `RequiresQuestionAndAnswer`
- `EnablePasswordRetrieval`
- `EnablePasswordReset`

The Membership framework's `RequiresQuestionAndAnswer` setting indicates whether users must specify a security question and answer when registering for an account. As we discussed in the *Creating User Accounts* tutorial, if `RequiresQuestionAndAnswer` is True (the default) then the CreateUserWizard's interface includes TextBox controls for the new user's security question and answer; if `RequiresQuestionAndAnswer` is False, no such information is collected. Similarly, if `RequiresQuestionAndAnswer` is True, then the PasswordRecovery control displays the Question view after the user has entered their username; the password is recovered only if the user enters the correct security answer. If `RequiresQuestionAndAnswer` is False, however, the PasswordRecovery control moves straight from the UserName view to the Success view.

After the user has provided his username - or his username and security answer, if `RequiresQuestionAndAnswer` is True - the PasswordRecovery emails the user his password. If the `EnablePasswordRetrieval` option is set to True, then the user is emailed their current password. If it is set to False and `EnablePasswordReset` is set to True, then the PasswordRecovery control generates a new, random password for the user, and emails this new password to them. If both `EnablePasswordRetrieval` and `EnablePasswordReset` are False, the PasswordRecovery control throws an exception.

> **NOTE**
> Recall that the `SqlMembershipProvider` stores users' passwords in one of three formats: Clear, Hashed (the default), or Encrypted. The storage mechanism used depends on the Membership configuration settings; the demo application uses the Hashed password format. When using the Hashed password format the `EnablePasswordRetrieval` option must be set to False because the system cannot determine the user's actual password from the hashed version stored in the database.

Figure 1 illustrates how the PasswordRecovery's interface and behavior is influenced by the Membership configuration.

Figure 1: The `RequiresQuestionAndAnswer`, `EnablePasswordRetrieval`, and `EnablePasswordReset` Influence the PasswordRecovery control's Appearance and Behavior (Click to view full-size image)

> **NOTE**
>
> In the *Creating the Membership Schema in SQL Server* tutorial we configured the Membership provider by setting `RequiresQuestionAndAnswer` to True, `EnablePasswordRetrieval` to False, and `EnablePasswordReset` to True.

Using the PasswordRecovery Control

Let's look at using the PasswordRecovery control in an ASP.NET page. Open `RecoverPassword.aspx` and drag and drop a PasswordRecovery control from the Toolbox onto the Designer; set its `ID` to `RecoverPwd`. Like the Login and CreateUserWizard Web controls, the PasswordRecovery control's views render a rich composite interface that includes Labels, TextBoxes, Buttons, and validation controls. You can customize the appearance of the views through the control's style properties or by converting the views into templates. I leave this as an exercise for the interested reader.

When a user visits this page she will enter her username and click the Submit button. Because we have set the `RequiresQuestionAndAnswer` property to True in our Membership configuration settings, the PasswordRecovery control will then display the Question view. After the user enters her correct security answer and clicks Submit,

the PasswordRecovery control will update the user's password to a randomly-generated one, and email this password to the email address on file. All of this was possible without us having to write a single line of code!

Before you test this page, there's one final piece of configuration to tend to: we need to specify the mail delivery settings in `Web.config`. The PasswordRecovery control relies on these settings for sending the email.

The mail delivery configuration is specified through the `<system.net>` element's `<mailSettings>` element. Use the `<smtp>` element to indicate the delivery method and the default From address. The following markup configures mail settings to use a network SMTP server named `smtp.example.com` on port 25 and with username/password credentials of username and password.

> **NOTE**
>
> `<system.net>` is a child element of the root `<configuration>` element and a sibling of `<system.web>`. Therefore, do not put the `<system.net>` element within the `<system.web>` element; instead, put it at the same level.

```
<configuration>
 ...
 <system.net>
 <mailSettings>
 <smtp deliveryMethod="Network" from="youraddress@example.com">
 <network
 host="smtp.example.com"
 userName="username"
 password="password"
 port="25" />
 </smtp>
 </mailSettings>
 </system.net>
</configuration>
```

In addition to using an SMTP server on the network, you can alternatively specify a pickup directory where email messages to be sent should be deposited.

Once you have configured the SMTP settings, visit the `RecoverPassword.aspx` page through a browser. First try entering a username that doesn't exist in the user store. As Figure 2 shows, the PasswordRecovery control displays a message indicating that the user information could not be accessed. The text of the message can be customized through the control's `UserNameFailureText` property.

Figure 2: An Error Message is Displayed if an Invalid Username is Entered (Click to view full-size image)

Now enter a username. Use the username of an account in the system with an email address that you can access and whose security answer you know. After entering the username and clicking Submit, the PasswordRecovery control displays its Question view. As with the UserName view, if you enter an incorrect answer the PasswordRecovery control displays an error message (see Figure 3). Use the `QuestionFailureText` property to customize this error message.

Figure 3: An Error Message is Displayed if the User Enters an Invalid Security Answer (Click to view full-size image)

Finally, enter the correct security answer and click Submit. Behind the scenes, the PasswordRecovery control generates a random password, assigns it to the user account, sends an email informing the user of their new password (see Figure 4), and then displays the Success view.

Figure 4: The User is Sent an Email with His New Password (Click to view full-size image)

Customizing the Email

The default email sent by the PasswordRecovery control is rather dull (see Figure 4). The message is sent from the account specified in the `<smtp>` element's `from` attribute with the subject Password and the plain-text body:

Please return to the site and log in using the following information.

User Name: *username*

Password: *password*

This message can be customized programmatically through an event handler for the PasswordRecovery control's `SendingMail` event, or declaratively through the `MailDefinition` property. Let's explore both of these options.

The `SendingMail` event is fired right before the email message is sent and is our last chance to programmatically

adjust the email message. When this event is raised, the event handler is passed an object of type `MailMessageEventArgs`, whose `Message` property contains a reference to the email about to be sent.

Create an event handler for the `SendingMail` event and add the following code, which programmatically adds `webmaster@example.com` to the CC list.

```
protected void RecoverPwd_SendingMail(object sender, MailMessageEventArgs e)
{
    e.Message.CC.Add("webmaster@example.com");
}
```

The email message can also be configured through declarative means. The PasswordRecovery's `MailDefinition` property is an object of type `MailDefinition`. The `MailDefinition` class offers a host of email-related properties, including `From`, `CC`, `Priority`, `Subject`, `IsBodyHtml`, `BodyFileName`, and others. For starters, set the `Subject` property to something more descriptive than the one used by default (Password), such as Your password has been reset...

To customize the body of the email message we need to create a separate email template file that contains the body's contents. Start by creating a new folder in the website named `EmailTemplates`. Next, add a new text file to this folder named `PasswordRecovery.txt` and add the following content:

```
Your password has been reset, <%UserName%>!

According to our records, you have requested that your password be reset. Your new
password is: <%Password%>

If you have any questions or trouble logging on please contact a site administrator.

Thank you!
```

Note the use of the placeholders `<%UserName%>` and `<%Password%>`. The PasswordRecovery control automatically replaces these two placeholders with the user's username and recovered password prior to sending the email.

Lastly, point the `MailDefinition`'s `BodyFileName` property to the email template we just created (`~/EmailTemplates/PasswordRecovery.txt`).

After making these changes revisit the `RecoverPassword.aspx` page and enter your username and security answer. You receive should an email that looks like the one in Figure 5. Note that `webmaster@example.com` has been CC'd and that the subject and body have been updated.

Figure 5: The Subject, Body, and CC List Have Been Updated (Click to view full-size image)

To send an HTML-formatted email set `IsBodyHtml` to True (the default is False) and update the email template to include HTML.

The `MailDefinition` property is not unique to the PasswordRecovery class. As we will see in Step 2, the ChangePassword control also offers a `MailDefinition` property. Moreover, the CreateUserWizard control includes such a property that you can configure to automatically send a welcome email message to new users.

> **NOTE**
> Currently there are no links in the left-hand navigation for reaching the `RecoverPassword.aspx` page. A user would only be interested in visiting this page if she was unable to successfully log on to the site. Therefore, update the `Login.aspx` page to include a link to the `RecoverPassword.aspx` page.

Programmatically Resetting a User's Password

When resetting a user's password the PasswordRecovery control calls the `MembershipUser` object's `ResetPassword` method. This method has two overloads:

- `ResetPassword` - resets a user's password. Use this overload if `RequiresQuestionAndAnswer` is False.
- `ResetPassword(securityAnswer)` - resets a user's password only if the supplied *securityAnswer* is correct. Use this overload if `RequiresQuestionAndAnswer` is True.

Both overloads return the new, randomly-generated password.

Like with the other methods in the Membership framework, the `ResetPassword` method delegates to the configured provider. The `SqlMembershipProvider` invokes the `aspnet_Membership_ResetPassword` stored procedure, passing in the user's username, the new password, and the supplied password answer, among other fields. The stored procedure ensures that the password answer matches and then updates the user's password.

A couple of low-level implementation notes:

- A locked out user cannot reset her password. However, an unapproved user may. We will discuss the locked out and approved states in more detail in the *Unlocking and Approving User* Accounts tutorial.
- If the password answer is incorrect, the user's failed password answer attempt count is incremented. If a specified number of invalid security answer attempts occur within a specified time window, the user is locked out.

A Word on How the Random Passwords are Generated

The randomly-generated passwords shown in the email messages in Figures 4 and 5 are created by the Membership class's `GeneratePassword` method. This method accepts two integer input paramters - *length* and *numberOfNonAlphanumericCharacters* - and returns a string at least *length* characters long with at least *numberOfNonAlphanumericCharacters* number of non-alphanumeric characters. When this method is called from within the Membership classes or Login-related Web controls, the values for these two parameters are determined by the Membership configuration's `MinRequiredPasswordLength` and `MinRequiredNonalphanumericCharacters` properties, which we set to 7 and 1, respectively.

The `GeneratePassword` method uses a cryptographically strong random number generator to ensure that there is no bias in what random characters are selected. Furthermore, `GeneratePassword` is `public`, meaning that you can use it directly from your ASP.NET application if you need to generate random strings or passwords.

> **NOTE**
>
> The `SqlMembershipProvider` class always generates a random password at least 14 characters long, so if `MinRequiredPasswordLength` is less than 14 then its value is ignored.

Step 2: Changing Passwords

The randomly-generated passwords are difficult to remember. Consider the password shown in Figure 4: `WWGUZv(f2yM:Bd`. Try committing that to memory! Needless to say, after a user is sent a randomly-generated password of this sort, she'll want to change the password to something more memorable.

Use the ChangePassword control to create an interface for a user to change her password. Much like the PasswordRecovery control, the ChangePassword control consists of two views: Change Password and Success. The Change Password view prompts the user for their old and new passwords. Upon supplying the correct old password and a new password that meets the minimum length and non-alphanumeric character requirements, the ChangePassword control updates the user's password and displays the Success view.

> **NOTE**
>
> The ChangePassword control modifies the user's password by invoking the `MembershipUser` object's `ChangePassword` method. The ChangePassword method accepts two `string` input parameters - *oldPassword* and *newPassword*- and updates the user's account with the *newPassword*, assuming the supplied *oldPassword* is correct.

Open the `ChangePassword.aspx` page and add a ChangePassword control to the page, naming it `ChangePwd`. At this point, the Design view should show the Change Password view (see Figure 6). Like with the PasswordRecovery control, you can toggle between the views via the control's Smart Tag. Furthermore, these views' appearances are customizable through the assorted style properties or by converting them to a template.

Figure 6: Add a ChangePassword Control to the Page (Click to view full-size image)

The ChangePassword control can update the currently logged in user's password *or* the password of another, specified user. As Figure 6 shows, the default Change Password view renders just three TextBox controls: one for the old password and two for the new password. This default interface is used to update the currently logged on user's password.

To use the ChangePassword control to update another user's password, set the control's `DisplayUserName` property to True. Doing so adds a fourth TextBox to the page, prompting for the username of the user whose password to change.

Setting `DisplayUserName` to True is useful if you want to let a logged out user change her password without having to log in. Personally, I think there's nothing wrong with requiring a user to login before allowing her to change her password. Therefore, leave `DisplayUserName` set to False (its default). In making this decision, however, we essentially are barring anonymous users from reaching this page. Update the site's URL authorization rules so as to deny anonymous users from visiting `ChangePassword.aspx`. If you need to refresh your memory on the URL authorization rule syntax, refer back to the *User-Based Authorization* tutorial.

> **NOTE**
>
> It may seem that the `DisplayUserName` property is useful for allowing administrators to change other users' passwords. However, even when `DisplayUserName` is set to True the correct old password must be known and entered. We will talk about techniques for allowing administrators to change users' passwords in Step 3.

Visit the `ChangePassword.aspx` page through a browser and change your password. Note that an error message is displayed if you enter a new password that fails to meet the password length and non-alphanumeric character requirements specified in the Membership configuration (see Figure 7).

Figure 7: Add a ChangePassword Control to the Page (Click to view full-size image)

Upon entering the correct old password and a valid new password, the logged on user's password is changed and the Success view displayed.

Sending a Confirmation Email

By default, the ChangePassword control does not send an email message to the user whose password was just updated. If you'd like to send an email, simply configure the control's `MailDefinition` property. Let's configure the ChangePassword control so that the user is sent an HTML-formatted email that contains their new password.

Start by creating a new file in the `EmailTemplates` folder named `ChangePassword.htm`. Add the following markup:

```
<html>
 <body>
 <h2>Your Password Has Been Changed!</h2>
 <p>
 This email confirms that your password has been changed.
 </p>
 <p>
 To log on to the site, use the following credentials:
 </p>
 <table>
 <tr>
 <td>
 <b>Username:</b>
 </td>
 <td>
 <%UserName%>
 </td>
 </tr>
 <tr>
 <td>
 <b>Password:</b>
 </td>
 <td>
 <%Password%>
 </td>
 </tr>
 </table>
 <p>
 If you have any questions or encounter any problems logging in,
 please contact a site administrator.
 </p>
 </body>
</html>
```

Next, set the ChangePassword control's `MailDefinition` property's `BodyFileName`, `IsBodyHtml`, and `Subject` properties to ~/EmailTemplates/ChangePassword.htm, True, and Your password has changed!, respectively.

After making these changes, revisit the page and change your password again. This time, the ChangePassword control sends a customized, HTML-formatted email to the user's email address on file (see Figure 8).

Figure 8: An Email Message Informs the User That Their Password has Changed (Click to view full-size image)

Step 3: Allowing Administrators to Change Users' Passwords

A common feature in applications that support user accounts is the ability for an administrative user to change other users' passwords. Sometimes this functionality is required because the system lacks the ability for users to change their own passwords. In such a case, the only way for a user to recover their forgotten password would be for the administrator to assign them a new password. With the PasswordRecovery and ChangePassword controls, however, administrative users need not busy themselves with changing users' passwords, as users are capable of doing this themselves.

But what if your client insists that administrative users should be able to change other users' passwords? Unfortunately, adding this functionality can be a bit of work. To change a user's password, both the old and new password must be supplied to the `MembershipUser` object's `ChangePassword` method, but an administrator shouldn't have to know a user's password in order to modify it.

One workaround is to first reset the user's password and then change it to the new password using code like the following:

```
MembershipUser usr = Membership.GetUser(username);
string resetPwd = usr.ResetPassword();
usr.ChangePassword(resetPwd, newPassword);
```

This code starts by retrieving information about *username*, which is the user whose password the administrator wishes to change. Next, the `ResetPassword` method is invoked, which assigns and the user a new, random password. This randomly-generated password is returned by the method and stored in the variable `resetPwd`. Now that we know the user's password, we can change it via a call to `ChangePassword`.

The problem is that this code only works if the Membership system configuration is set such that `RequiresQuestionAndAnswer` is False. If `RequiresQuestionAndAnswer` is True, as it is with our application, then the `ResetPassword` method needs to be passed the security answer, otherwise it will throw an exception.

If the Membership framework is configured to require a security question and answer, and yet your client insists that administrators be able to change users' passwords, you have three options:

- Throw your hands in the air and tell your client that this is just one thing that cannot be done.
- Set `RequiresQuestionAndAnswer` to False. This results in a less secure application. Imagine that a nefarious user has gained access to another user's email inbox. Perhaps the compromised user has left their desk to go to lunch and didn't lock their workstation, or maybe they accessed their email from a public terminal and didn't sign out. In either case, the nefarious user can visit the `RecoverPassword.aspx` page and enter the user's username. The system will then email the recovered password without prompting for the security answer.
- Bypass the abstraction layer created by the Membership framework and work directly with the SQL Server database. The Membership schema includes a stored procedure named `aspnet_Membership_SetPassword` that sets a user's password and does not require the security answer or old password in order to accomplish its task.

None of these options are particularly appealing, but that's how the life of a developer goes sometimes.

I went ahead and implemented the third approach, writing code that bypasses the `Membership` and `MembershipUser` classes and operates directly against the `SecurityTutorials` database.

NOTE

By working directly with the database, the encapsulation provided by the Membership framework is shattered. This decision ties us to the `SqlMembershipProvider`, making our code less portable. Furthermore, this code may not work as expected in future versions of ASP.NET if the Membership schema changes. This approach is a workaround and, like most workarounds, is not an example of best practices.

The code has some unattractive bits and is quite lengthy. Therefore, I don't want to clutter this tutorial with an in-depth examination of it. If you are interested in learning more, download the code for this tutorial and visit the `~/Administration/ManageUsers.aspx` page. This page, which we created in the preceding tutorial, lists each user. I've updated the GridView to include a link to the `UserInformation.aspx` page, passing the selected user's username through the querystring. The `UserInformation.aspx` page displays information about the selected user and TextBoxes for changing their password (see Figure 9).

After entering the new password, confirming it in the second TextBox, and clicking the Update User Button, a postback ensues and the `aspnet_Membership_SetPassword` stored procedure is invoked, updating the user's password. I encourage those readers interested in this functionality to become more familiar with the code and try extending the functionality to include sending an email to the user whose password was changed.

Figure 9: An Administrator May Change a User's Password (Click to view full-size image)

NOTE

The `UserInformation.aspx` page currently only works if the Membership framework is configured to store passwords in Clear or Hashed format. It lacks the code to encrypt the new password, although you are invited to add this functionality. The way I recommend adding the necessary code is to use a decompiler like Reflector to examine the source code for methods in the .NET Framework; start by examining the `SqlMembershipProvider` class's `ChangePassword` method. This is the technique I used to write the code for creating a hash of the password.

Summary

ASP.NET offers two controls to help users manage their password. The PasswordRecovery control is useful for those who have forgotten their passwords. Depending on the Membership framework's configuration, the user is either emailed their existing password or a new, randomly-generated password. The ChangePassword control enables a user to update their password.

Like the Login and CreateUserWizard controls, the PasswordRecovery and ChangePassword controls render a rich

user interface without having to write a lick of declarative markup or line of code. If the default user interface doesn't meet your needs, you can customize it through a variety of style properties. Alternatively, the controls' interfaces may be converted into templates, for an even finer degree of control. Behind the scenes these controls use the Membership API, invoking the `MembershipUser` object's `ResetPassword` and `ChangePassword` methods.

Happy Programming!

> This tutorial shows how to build a web page for administrators to manage users' locked out and approved statuses. We will also see how to approve new users only after they have verified their email address.

Introduction

Along with a username, password, and email, each user account has two status fields that dictate whether the user can log into the site: locked out and approved. A user is automatically locked out if they provide invalid credentials a specified number of times within a specified number of minutes (the default settings lock a user out after 5 invalid login attempts within 10 minutes). The approved status is useful in scenarios where some action must transpire before a new user is able to log on to the site. For example, a user might need to first verify their email address or be approved by an administrator before being able to login.

Because a locked out or unapproved user cannot login, it's only natural to wonder how these statuses can be reset. ASP.NET does not include any built-in functionality or Web controls for managing users' locked out and approved statuses, in part because these decisions need to be handled on a site-by-site basis. Some sites might automatically approve all new user accounts (the default behavior). Others have an administrator approve new accounts or do not approve users until they visit a link sent to the email address provided when they signed up. Likewise, some sites may lock out users until an administrator resets their status, while other sites send an email to the locked out user with a URL they can visit to unlock their account.

This tutorial shows how to build a web page for administrators to manage users' locked out and approved statuses. We will also see how to approve new users only after they have verified their email address.

Step 1: Managing Users' Locked Out and Approved Statuses

In the *Building an Interface to Select One User Account from Many* tutorial we constructed a page that listed each user account in a paged, filtered GridView. The grid lists each user's name and email, their approved and locked out statuses, whether they're currently online, and any comments about the user. To manage users' approved and locked out statuses, we could make this grid editable. To change a user's approved status, the administrator would first locate the user account and then edit the corresponding GridView row, checking or unchecking the approved checkbox. Alternatively, we could manage the approved and locked out statuses through a separate ASP.NET page.

For this tutorial let's use two ASP.NET pages: `ManageUsers.aspx` and `UserInformation.aspx`. The idea here is that `ManageUsers.aspx` lists the user accounts in the system, while `UserInformation.aspx` enables the administrator to manage the approved and locked out statuses for a specific user. Our first order of business is to augment the GridView in `ManageUsers.aspx` to include a HyperLinkField, which renders as a column of links. We want each link to point to `UserInformation.aspx?user=UserName`, where *UserName* is the name of the user to edit.

> **NOTE**
>
> If you downloaded the code for the *Recovering and Changing Passwords* tutorial you may have noticed that the `ManageUsers.aspx` page already contains a set of "Manage" links and the `UserInformation.aspx` page provides an interface for changing the selected user's password. I decided not to replicate that functionality in the code associated with this tutorial because it worked by circumventing the Membership API and operating directly with the SQL Server database to change a user's password. This tutorial starts from scratch with the `UserInformation.aspx` page.

Adding "Manage" Links to the `UserAccounts` GridView

Open the `ManageUsers.aspx` page and add a HyperLinkField to the `UserAccounts` GridView. Set the HyperLinkField's `Text` property to "Manage" and its `DataNavigateUrlFields` and `DataNavigateUrlFormatString` properties to `UserName` and "UserInformation.aspx?user={0}", respectively. These settings configure the HyperLinkField such that all of the hyperlinks display the text "Manage", but each link passes in the appropriate *UserName* value into the querystring.

After adding the HyperLinkField to the GridView, take a moment to view the `ManageUsers.aspx` page through a browser. As Figure 1 shows, each GridView row now includes a "Manage" link. The "Manage" link for Bruce points to `UserInformation.aspx?user=Bruce`, whereas the "Manage" link for Dave points to `UserInformation.aspx?user=Dave`.

Figure 1: The HyperLinkField Adds a "Manage" Link for Each User Account (Click to view full-size image)

We will create the user interface and code for the `UserInformation.aspx` page in a moment, but first let's talk about how to programmatically change a user's locked out and approved statuses. The `MembershipUser` class has `IsLockedOut` and `IsApproved` properties. The `IsLockedOut` property is read-only. There is no mechanism to programmatically lock out a user; to unlock a user, use the `MembershipUser` class's `UnlockUser` method. The `IsApproved` property is readable and writeable. To save any changes to this property, we need to call the `Membership` class's `UpdateUser` method, passing in the modified `MembershipUser` object.

Because the `IsApproved` property is readable and writeable, a CheckBox control is probably the best user interface element for configuring this property. However, a CheckBox will not work for the `IsLockedOut` property because an administrator cannot lock out a user, she may only unlock a user. A suitable user interface for the `IsLockedOut` property is a Button that, when clicked, unlocks the user account. This Button should only be enabled if the user is locked out.

Creating the `UserInformation.aspx` Page

We are now ready to implement the user interface in `UserInformation.aspx`. Open this page and add the

following Web controls:

- A HyperLink control that, when clicked, returns the administrator to the `ManageUsers.aspx` page.
- A Label Web control for displaying the selected user's name. Set this Label's `ID` to `UserNameLabel` and clear out its `Text` property.
- A CheckBox control named `IsApproved`. Set its `AutoPostBack` property to `true`.
- A Label control for displaying the user's last locked out date. Name this Label `LastLockedOutDateLabel` and clear out its `Text` property.
- A Button for unlocking the user. Name this Button `UnlockUserButton` and set its `Text` property to "Unlock User".
- A Label control for displaying status messages, such as, "The user's approved status has been updated." Name this control `StatusMessage`, clear out its `Text` property, and set its `CssClass` property to `Important`. (The `Important` CSS class is defined in the `Styles.css` stylesheet file; it displays the corresponding text in a large, red font.)

After adding these controls, the Design view in Visual Studio should look similar to the screen shot in Figure 2.

Figure 2: Create the User Interface for `UserInformation.aspx` (Click to view full-size image)

With the user interface complete, our next task is to set the `IsApproved` CheckBox and other controls based on the selected user's information. Create an event handler for the page's `Load` event and add the following code:

```
protected void Page_Load(object sender, EventArgs e)
{
     if (!Page.IsPostBack)
     {

          // If querystring value is missing, send the user to ManageUsers.aspx
          string userName = Request.QueryString["user"];
          if (string.IsNullOrEmpty(userName))
               Response.Redirect("ManageUsers.aspx");

          // Get information about this user
          MembershipUser usr = Membership.GetUser(userName);
          if (usr == null)
               Response.Redirect("ManageUsers.aspx");

          UserNameLabel.Text = usr.UserName;
          IsApproved.Checked = usr.IsApproved;
          if (usr.LastLockoutDate.Year < 2000)

               LastLockoutDateLabel.Text = string.Empty;
          else
               LastLockoutDateLabel.Text = usr.LastLockoutDate.ToShortDateString();

          UnlockUserButton.Enabled = usr.IsLockedOut;
     }
}
```

The above code starts by ensuring that this is the first visit to the page and not a subsequent postback. It then reads the username passed through the `user` querystring field and retrieves information about that user account via the `Membership.GetUser(username)` method. If no username was supplied through the querystring, or if the specified user could not be found, the administrator is sent back to the `ManageUsers.aspx` page.

The `MembershipUser` object's `UserName` value is then displayed in the `UserNameLabel` and the `IsApproved` CheckBox is checked based on the `IsApproved` property value.

The `MembershipUser` object's `LastLockoutDate` property returns a `DateTime` value indicating when the user was last locked out. If the user has never been locked out, the value returned depends on the Membership provider. When a new account is created, the `SqlMembershipProvider` sets the `aspnet_Membership` table's `LastLockoutDate` field to `1754-01-01 12:00:00 AM`. The above code displays an empty string in the `LastLockoutDateLabel` if the `LastLockoutDate` property occurs before year 2000; otherwise, the date portion of the `LastLockoutDate` property is displayed in the Label. The `UnlockUserButton'` s `Enabled` property is set to the user's locked out status, meaning that this Button will only be enabled if the user is locked out.

Take a moment to test the `UserInformation.aspx` page through a browser. You will, of course, need to start at `ManageUsers.aspx` and select a user account to manage. Upon arriving at `UserInformation.aspx`, note that the `IsApproved` CheckBox is only checked if the user is approved. If the user has ever been locked out, their last locked out date is displayed. The Unlock User button is enabled only if the user is currently locked out. Checking or unchecking the `IsApproved` CheckBox or clicking the Unlock User button causes a postback, but no modifications are made to the user account because we've yet to create event handlers for these events.

Return to Visual Studio and create event handlers for the `IsApproved` CheckBox's `CheckedChanged` event and the `UnlockUser` Button's `Click` event. In the `CheckedChanged` event handler, set the user's `IsApproved` property to the `Checked` property of the CheckBox and then save the changes via a call to `Membership.UpdateUser`. In the `Click` event handler, simply call the `MembershipUser` object's `UnlockUser` method. In both event handlers, display a suitable message in the `StatusMessage` Label.

```
protected void IsApproved_CheckedChanged(object sender, EventArgs e)
{
     // Toggle the user's approved status
     string userName = Request.QueryString["user"];
     MembershipUser usr = Membership.GetUser(userName);
     usr.IsApproved = IsApproved.Checked;
     Membership.UpdateUser(usr);
     StatusMessage.Text = "The user's approved status has been updated.";
}

protected void UnlockUserButton_Click(object sender, EventArgs e)
{
     // Unlock the user account
     string userName = Request.QueryString["user"];
     MembershipUser usr = Membership.GetUser(userName);

     usr.UnlockUser();
     UnlockUserButton.Enabled = false;
     StatusMessage.Text = "The user account has been unlocked.";
}
```

Testing the `UserInformation.aspx` Page

With these event handlers in place, revisit the page and unapproved a user. As Figure 3 shows, you should see a brief message on the page indicating that the user's `IsApproved` property was successfully modified.

Figure 3: Chris has been Unapproved (Click to view full-size image)

Next, logout and try to login as the user whose account was just unapproved. Because the user is not approved, they cannot login. By default, the Login control displays the same message if the user cannot login, regardless of the reason. But in the *Validating User Credentials Against the Membership User Store* tutorial we looked at enhancing the Login control to display a more appropriate message. As Figure 4 shows, Chris is shown a message explaining that he cannot login because his account is not yet approved.

Figure 4: Chris Cannot Login Because His Account is Unapproved (Click to view full-size image)

To test the locked out functionality, attempt to login as an approved user, but use an incorrect password. Repeat this process the necessary number of times until the user's account has been locked out. The Login control was also updated to show a custom message if attempting to login from a locked out account. You know that an account has been locked out once you start seeing the following message at the login page: "Your account has been locked out because of too many invalid login attempts. Please contact the administrator to have your account unlocked."

Return to the `ManageUsers.aspx` page and click the Manage link for the locked out user. As Figure 5 shows, you should see a value in the `LastLockedOutDateLabel` the Unlock User button should be enabled. Click the Unlock User button to unlock the user account. Once you have unlocked the user, they will be able to login again.

Figure 5: Dave Has Been Locked Out of the System (Click to view full-size image)

Step 2: Specifying New Users' Approved Status

The approved status is useful in scenarios where you want some action to be performed before a new user is able

to login and access the user-specific features of the site. For example, you may be running a private website where all pages, except for the login and signup pages, are accessible only to authenticated users. But what happens if a stranger reaches your website, finds the signup page, and creates an account? To prevent this from happening you could move the signup page to an `Administration` folder, and require that an administrator manually create each account. Alternatively, you could allow anyone to signup, but prohibit site access until an administrator approves the user account.

By default, the CreateUserWizard control approves new accounts. You can configure this behavior using the control's `DisableCreatedUser` property. Set this property to `true` to not approve new user accounts.

> **NOTE**
> By default the CreateUserWizard control automatically logs on the new user account. This behavior is dictated by the control's `LoginCreatedUser` property. Because unapproved users cannot login to the site, when `DisableCreatedUser` is `true` the new user account is not logged into the site, regardless of the value of the `LoginCreatedUser` property.

If you are programmatically creating new user accounts via the `Membership.CreateUser` method, to create an unapproved user account use one of the overloads that accept the new user's `IsApproved` property value as an input parameter.

Step 3: Approving Users By Verifying their Email Address

Many websites that support user accounts do not approve new users until they verify the email address they supplied when registering. This verification process is commonly used to thwart bots, spammers, and other ne'er-do-wells as it requires a unique, verified email address and adds an extra step in the signup process. With this model, when a new user signs up they are sent an email message that includes a link to a verification page. By visiting the link the user has proven that they received the email and, therefore, that the email address provided is valid. The verification page is responsible for approving the user. This may happen automatically, thereby approving any user who reaches this page, or only after the user provides some additional information, such as a CAPTCHA.

To accommodate this workflow, we need to first update the account creation page so that new users are unapproved. Open the `EnhancedCreateUserWizard.aspx` page in the `Membership` folder and set the CreateUserWizard control's `DisableCreatedUser` property to `true`.

Next, we need to configure the CreateUserWizard control to send an email to the new user with instructions on how to verify their account. In particular, we will include a link in the email to the `Verification.aspx` page (which we've yet to create), passing in the new user's `UserId` through the querystring. The `Verification.aspx` page will lookup the specified user and mark them approved.

Sending a Verification Email to New Users

To send an email from the CreateUserWizard control, configure its `MailDefinition` property appropriately. As discussed in the previous tutorial, the ChangePassword and PasswordRecovery controls include a `MailDefinition` property that works in the same manner as the CreateUserWizard control's.

> **NOTE**
> To use the `MailDefinition` property you need to specify mail delivery options in `Web.config`. For more information, refer to Sending Email in ASP.NET.

Start by creating a new email template named `CreateUserWizard.txt` in the `EmailTemplates` folder. Use the following text for the template:

```
Hello <%UserName%>! Welcome aboard.

Your new account is almost ready, but before you can login you must first visit:
<%VerificationUrl%>

Once you have visited the verification URL you will be redirected to the login page.

If you have any problems or questions, please reply to this email.

Thanks!
```

Set the `MailDefinition'` s `BodyFileName` property to "~/EmailTemplates/CreateUserWizard.txt" and its `Subject` property to "Welcome to My Website! Please activate your account."

Note that the `CreateUserWizard.txt` email template includes a `<%VerificationUrl%>` placeholder. This is where the URL for the `Verification.aspx` page will be placed. The CreateUserWizard automatically replaces the `<%UserName%>` and `<%Password%>` placeholders with the new account's username and password, but there is no built-in `<%VerificationUrl%>` placeholder. We need to manually replace it with the appropriate verification URL.

To accomplish this, create an event handler for the CreateUserWizard's `SendingMail` event and add the following code:

```
protected void NewUserWizard_SendingMail(object sender, MailMessageEventArgs e)
{
     // Get the UserId of the just-added user
     MembershipUser newUser = Membership.GetUser(NewUserWizard.UserName);

     Guid newUserId = (Guid)newUser.ProviderUserKey;

     // Determine the full verification URL (i.e., http://yoursite.com/Verification.aspx?ID=...)
     string urlBase = Request.Url.GetLeftPart(UriPartial.Authority) +
          Request.ApplicationPath;

     string verifyUrl = "/Verification.aspx?ID=" + newUserId.ToString();
     string fullUrl = urlBase + verifyUrl;

     // Replace <%VerificationUrl%> with the appropriate URL and querystring
     e.Message.Body = e.Message.Body.Replace("<%VerificationUrl%>", fullUrl);
}
```

The `SendingMail` event fires after the `CreatedUser` event, meaning that by the time the above event handler executes the new user account has already been created. We can access the new user's `UserId` value by calling the `Membership.GetUser` method, passing in the `UserName` entered into the CreateUserWizard control. Next, the verification URL is formed. The statement `Request.Url.GetLeftPart(UriPartial.Authority)` returns the `http://yourserver.com` portion of the URL; `Request.ApplicationPath` returns path where the application is rooted. The verification URL is then defined as `Verification.aspx?ID=userId`. These two strings are then concatenated to form the complete URL. Finally, the email message body (`e.Message.Body`) has all occurrences of `<%VerificationUrl%>` replaced with the full URL.

The net effect is that new users are unapproved, meaning that they cannot log into the site. Furthermore, they are automatically sent an email with a link to the verification URL (see Figure 6).

Figure 6: The New User Receives an Email with a Link to the Verification URL (Click to view full-size image)

> **NOTE**
>
> The CreateUserWizard control's default CreateUserWizard step displays a message informing the user their account has been created and displays a Continue button. Clicking this takes the user to the URL specified by the control's `ContinueDestinationPageUrl` property. The CreateUserWizard in `EnhancedCreateUserWizard.aspx` is configured to send new users to the `~/Membership/AdditionalUserInfo.aspx`, which prompts the user for their hometown, homepage URL, and signature. Because this information can only be added by logged on users, it makes sense to update this property to send users back to the site's homepage (`~/Default.aspx`). Moreover, the `EnhancedCreateUserWizard.aspx` page or the CreateUserWizard step should be augmented to inform the user that they have been sent a verification email and their account won't be activated until they follow the instructions in this email. I leave these modifications as an exercise for the reader.

Creating the Verification Page

Our final task is to create the `Verification.aspx` page. Add this page to the root folder, associating it with the `Site.master` master page. As we've done with most of the previous content pages added to the site, remove the Content control that references the `LoginContent` ContentPlaceHolder so that the content page uses the master page's default content.

Add a Label Web control to the `Verification.aspx` page, set its `ID` to `StatusMessage` and clear out its text property. Next, create the `Page_Load` event handler and add the following code:

```
protected void Page_Load(object sender, EventArgs e)
{
     if (string.IsNullOrEmpty(Request.QueryString["ID"]))
          StatusMessage.Text = "The UserId was not included in the querystring...";
     else
     {
          Guid userId;
          try
          {
               userId = new Guid(Request.QueryString["ID"]);
          }

          catch
          {
               StatusMessage.Text = "The UserId passed into the querystring is not in the
                    proper format...";
               return;
          }

          MembershipUser usr = Membership.GetUser(userId);
          if (usr == null)
               StatusMessage.Text = "User account could not be found...";
          else
          {
               // Approve the user
               usr.IsApproved = true;

               Membership.UpdateUser(usr);
               StatusMessage.Text = "Your account has been approved.
                    Please <a href=\"Login.aspx\">login</a> to the site.";
          }
     }
}
```

The bulk of the above code verifies that the `UserId` supplied through the querystring exists, that it is a valid `Guid` value, and that it references an existing user account. If all of these checks pass, the user account is approved; otherwise, a suitable status message is displayed.

Figure 7 shows the `Verification.aspx` page when visited through a browser.

Figure 7: The New User's Account is Now Approved (Click to view full-size image)

Summary

All Membership user accounts have two statuses that determine whether the user can log into the site: `IsLockedOut` and `IsApproved`. Both of these properties must be `true` for the user to login.

The user's locked out status is used as a security measure to reduce the likelihood of a hacker breaking into a site

through brute force methods. Specifically, a user is locked out if there are a certain number of invalid login attempts within a certain window of time. These bounds are configurable through the Membership provider settings in `Web.config`.

The approved status is commonly used as a means to prohibit new users from logging in until some action has transpired. Perhaps the site requires that new accounts first be approved by the administrator or, as we saw in Step 3, by verifying their email address.

Happy Programming!

Building an Interface to Select One User Account from Many (VB)

9/16/2020 • 17 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

In this tutorial we will build a user interface with a paged, filterable grid. In particular, our user interface will consist of a series of LinkButtons for filtering the results based on the starting letter of the username, and a GridView control to show the matching users. We'll start by listing all of the user accounts in a GridView. Then, in Step 3, we will add the filter LinkButtons. Step 4 looks at paging the filtered results. The interface constructed in Steps 2 through 4 will be used in the subsequent tutorials to perform administrative tasks for a particular user account.

Introduction

In the *Assigning Roles to Users* tutorial, we created a rudimentary interface for an administrator to select a user and manage her roles. Specifically, the interface presented the administrator with a drop-down list of all of the users. Such an interface is suitable when there are but a dozen or so user accounts, but is unwieldy for sites with hundreds or thousands of accounts. A paged, filterable grid is more suitable user interface for websites with large user bases.

In this tutorial we will build such a user interface. In particular, our user interface will consist of a series of LinkButtons for filtering the results based on the starting letter of the username, and a GridView control to show the matching users. We'll start by listing all of the user accounts in a GridView. Then, in Step 3, we will add the filter LinkButtons. Step 4 looks at paging the filtered results. The interface constructed in Steps 2 through 4 will be used in the subsequent tutorials to perform administrative tasks for a particular user account.

Let's get started!

Step 1: Adding New ASP.NET Pages

In this tutorial and the next two we will be examining various administration-related functions and capabilities. We will need a series of ASP.NET pages to implement the topics examined throughout these tutorials. Let's create these pages and update the site map.

Start by creating a new folder in the project named `Administration`. Next, add two new ASP.NET pages to the folder, linking each page with the `Site.master` master page. Name the pages:

- `ManageUsers.aspx`
- `UserInformation.aspx`

Also add two pages to the website's root directory: `ChangePassword.aspx` and `RecoverPassword.aspx`.

These four pages should, at this point, have two Content controls, one for each of the master page's ContentPlaceHolders: `MainContent` and `LoginContent`.

```
<asp:Content ID="Content1" ContentPlaceHolderID="MainContent" Runat="Server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="LoginContent" Runat="Server">
</asp:Content>
```

We want to show the master page's default markup for the `LoginContent` ContentPlaceHolder for these pages. Therefore, remove the declarative markup for the `Content2` Content control. After doing so, the pages' markup should contain just one Content control.

The ASP.NET pages in the `Administration` folder are intended solely for administrative users. We added an Administrators role to the system in the *Creating and Managing Roles* tutorial; restrict access to these two pages to this role. To accomplish this, add a `Web.config` file to the `Administration` folder and configure its `<authorization>` element to admit users in the Administrators role and to deny all others.

```
<?xml version="1.0"?>
<configuration>
 <system.web>
 <authorization>
 <allow roles="Administrators" />
 <deny users="*"/>
 </authorization>
 </system.web>
</configuration>
```

At this point your project's Solution Explorer should look similar to the screen shot shown in Figure 1.

Figure 1: Four New Pages and a `Web.config` File Have Been Added to the Website (Click to view full-size image)

Finally, update the site map (`Web.sitemap`) to include an entry to the `ManageUsers.aspx` page. Add the following XML after the `<siteMapNode>` we added for the Roles tutorials.

```
<siteMapNode title="User Administration" url="~/Administration/ManageUsers.aspx"/>
```

With the site map updated, visit the site through a browser. As Figure 2 shows, the navigation on the left now includes items for the Administration tutorials.

Figure 2: The Site Map Includes a Node Titled User Administration (Click to view full-size image)

Step 2: Listing All User Accounts in a GridView

Our end goal for this tutorial is to create a paged, filterable grid through which an administrator can select a user account to manage. Let's start by listing *all* users in a GridView. Once this is complete, we will add the filtering and paging interfaces and functionality.

Open the `ManageUsers.aspx` page in the `Administration` folder and add a GridView, setting its `ID` to `UserAccounts` In a moment, we will write code to bind the set of user accounts to the GridView using the `Membership` class's `GetAllUsers` method. As discussed in earlier tutorials, the `GetAllUsers` method returns a `MembershipUserCollection` object, which is a collection of `MembershipUser` objects. Each `MembershipUser` in the collection includes properties like `UserName`, `Email`, `IsApproved`, and so on.

In order to display the desired user account information in the GridView, set the GridView's `AutoGenerateColumns` property to False and add BoundFields for the `UserName`, `Email`, and `Comment` properties and CheckBoxFields for the `IsApproved`, `IsLockedOut`, and `IsOnline` properties. This configuration can be applied through the control's declarative markup or via the Fields dialog box. Figure 3 shows a screen shot of the Fields dialog box after the Auto-generate fields checkbox has been unchecked and the BoundFields and CheckBoxFields have been added and configured.

Figure 3: Add Three BoundFields and Three CheckBoxFields to the GridView (Click to view full-size image)

After configuring your GridView, ensure that its declarative markup resembles the following:

```
<asp:GridView ID="UserAccounts" runat="server" AutoGenerateColumns="False">
 <Columns>
 <asp:BoundField DataField="UserName" HeaderText="UserName" />
 <asp:BoundField DataField="Email" HeaderText="Email" />
 <asp:CheckBoxField DataField="IsApproved" HeaderText="Approved?" />
 <asp:CheckBoxField DataField="IsLockedOut" HeaderText="Locked Out?" />
 <asp:CheckBoxField DataField="IsOnline" HeaderText="Online?" />
 <asp:BoundField DataField="Comment" HeaderText="Comment" />
 </Columns>
</asp:GridView>
```

Next, we need to write code that binds the user accounts to the GridView. Create a method named `BindUserAccounts` to perform this task and then call it from the `Page_Load` event handler on the first page visit.

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Not Page.IsPostBack Then
 BindUserAccounts()
 End If
End Sub

Private Sub BindUserAccounts()
 UserAccounts.DataSource = Membership.GetAllUsers()
 UserAccounts.DataBind()
End Sub
```

Take a moment to test the page through a browser. As Figure 4 shows, the `UserAccounts` GridView lists the username, email address, and other pertinent account information for all users in the system.

Figure 4: The User Accounts are Listed in the GridView (Click to view full-size image)

Step 3: Filtering the Results by the First Letter of the Username

Currently the `UserAccounts` GridView shows *all* of the user accounts. For websites with hundreds or thousands of user accounts, it is imperative that user be able to quickly pare down the displayed accounts. This can be accomplished by adding filtering LinkButtons to the page. Let's add 27 LinkButtons to the page: one titled All along with one LinkButton for each letter of the alphabet. If a visitor clicks the All LinkButton, the GridView will show all of the users. If they click a particular letter, only those users whose username starts with the selected letter will be displayed.

Our first task is to add the 27 LinkButton controls. One option would be to create the 27 LinkButtons declaratively, one at a time. A more flexible approach is to use a Repeater control with an `ItemTemplate` that renders a LinkButton and then binds the filtering options to the Repeater as a `String` array.

Start by adding a Repeater control to the page above the `UserAccounts` GridView. Set the Repeater's `ID` property to `FilteringUI` Configure the Repeater's templates so that its `ItemTemplate` renders a LinkButton whose `Text` and `CommandName` properties are bound to the current array element. As we saw in the *Assigning Roles to Users* tutorial, this can be accomplished using the `Container.DataItem` databinding syntax. Use the Repeater's `SeparatorTemplate` to display a vertical line between each link.

```
<asp:Repeater ID="FilteringUI" runat="server">
 <ItemTemplate>
 <asp:LinkButton runat="server" ID="lnkFilter"
 Text='<%# Container.DataItem %>'
 CommandName='<%# Container.DataItem %>'></asp:LinkButton>
 </ItemTemplate>
 <SeparatorTemplate>|</SeparatorTemplate>
</asp:Repeater>
```

To populate this Repeater with the desired filtering options, create a method named `BindFilteringUI`. Be sure to call this method from the `Page_Load` event handler on the first page load.

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
 If Not Page.IsPostBack Then
 BindUserAccounts()
 BindFilteringUI()
 End If
End Sub

Private Sub BindFilteringUI()
 Dim filterOptions() As String = {"All", "A", "B", "C", "D", "E", "F", "G", "H", "I", "J", "K", "L", "M",
"N", "O", "P", "Q", "R", "S", "T", "U", "V", "W", "X", "Y", "Z"}
 FilteringUI.DataSource = filterOptions
 FilteringUI.DataBind()
End Sub
```

This method specifies the filtering options as elements in the `String` array `filterOptions` For each element in the array, the Repeater will render a LinkButton with its `Text` and `CommandName` properties assigned to the value of the array element.

Figure 5 shows the `ManageUsers.aspx` page when viewed through a browser.

Figure 5: The Repeater Lists 27 Filtering LinkButtons (Click to view full-size image)

> **NOTE**
>
> Usernames may start with any character, including numbers and punctuation. In order to view these accounts, the administrator will have to use the All LinkButton option. Alternatively, you could add a LinkButton to return all user accounts that start with a number. I leave this as an exercise for the reader.

Clicking any of the filtering LinkButtons causes a postback and raises the Repeater's `ItemCommand` event, but there's no change in the grid because we've yet to write any code to filter the results. The `Membership` class includes a `FindUsersByName` method that returns those user accounts whose username matches a specified search pattern. We can use this method to retrieve just those user accounts whose usernames start with the letter specified by the `CommandName` of the filtered LinkButton that was clicked.

Start by updating the `ManageUser.aspx` page's code-behind class so that it includes a property named `UsernameToMatch` This property persists the username filter string across postbacks:

```
Private Property UsernameToMatch() As String
 Get
 Dim o As Object = ViewState("UsernameToMatch")
 If o Is Nothing Then
 Return String.Empty
 Else
 Return o.ToString()
 End If
 End Get
 Set(ByVal Value As String)
 ViewState("UsernameToMatch") = Value
 End Set
End Property
```

The `UsernameToMatch` property stores its value it is assigned into the `ViewState` collection using the key 'UsernameToMatch'. When this property's value is read, it checks to see if a value exists in the `ViewState` collection; if not, it returns the default value, an empty string. The `UsernameToMatch` property exhibits a common pattern, namely persisting a value to view state so that any changes to the property are persisted across postbacks. For more information on this pattern, read Understanding ASP.NET View State.

Next, update the `BindUserAccounts` method so that instead of calling `Membership.GetAllUsers`, it calls `Membership.FindUsersByName`, passing in the value of the `UsernameToMatch` property appended with the SQL wildcard character, %.

```
Private Sub BindUserAccounts()
 UserAccounts.DataSource = Membership.FindUsersByName(Me.UsernameToMatch &"%")
 UserAccounts.DataBind()
End Sub
```

To display just those users whose username starts with the letter A, set the `UsernameToMatch` property to A and then call `BindUserAccounts` This would result in a call to `Membership.FindUsersByName("A%")`, which will return all users whose username starts with A. Likewise, to return *all* users, assign an empty string to the `UsernameToMatch` property so that the `BindUserAccounts` method will invoke `Membership.FindUsersByName("%")`, thereby returning all user accounts.

Create an event handler for the Repeater's `ItemCommand` event. This event is raised whenever one of the filter LinkButtons is clicked; it is passed the clicked LinkButton's `CommandName` value through the `RepeaterCommandEventArgs` object. We need to assign the appropriate value to the `UsernameToMatch` property and then call the `BindUserAccounts` method. If the `CommandName` is All, assign an empty string to `UsernameToMatch` so that all user accounts are displayed. Otherwise, assign the `CommandName` value to `UsernameToMatch`

```
Protected Sub FilteringUI_ItemCommand(ByVal source As Object, ByVal e As
System.Web.UI.WebControls.RepeaterCommandEventArgs) Handles FilteringUI.ItemCommand
 If e.CommandName = "All" Then
 Me.UsernameToMatch = String.Empty
 Else
 Me.UsernameToMatch = e.CommandName
 End If

 BindUserAccounts()
End Sub
```

With this code in place, test out the filtering functionality. When the page is first visited, all user accounts are displayed (refer back to Figure 5). Clicking the A LinkButton causes a postback and filters the results, displaying only those user accounts that start with A .

Figure 6: Use the Filtering LinkButtons to Display those Users Whose Username Starts with a Certain Letter (Click to view full-size image)

Step 4: Updating the GridView to Use Paging

The GridView shown in Figures 5 and 6 lists all of the records returned from the `FindUsersByName` method. If there are hundreds or thousands of user accounts this can lead to information overload when viewing all of the accounts (as is the case when clicking the All LinkButton or when initially visiting the page). To help present the user accounts in more manageable chunks, let's configure the GridView to display 10 user accounts at a time.

The GridView control offers two types of paging:

- **Default paging** - easy to implement, but inefficient. In a nutshell, with default paging the GridView expects *all* of the records from its data source. It then only displays the appropriate page of records.
- **Custom paging** - requires more work to implement, but is more efficient than default paging because with custom paging the data source returns only the precise set of records to display.

The performance difference between default and custom paging can be quite substantial when paging through thousands of records. Because we are building this interface assuming that there may be hundreds or thousands of user accounts, let's use custom paging.

> **NOTE**
> For a more thorough discussion on the differences between default and custom paging, as well as the challenges involved in implementing custom paging, refer to Efficiently Paging Through Large Amounts of Data. For some analysis of the performance difference between default and custom paging, see Custom Paging in ASP.NET with SQL Server 2005.

To implement custom paging we first need some mechanism by which to retrieve the precise subset of records being displayed by the GridView. The good news is that the `Membership` class's `FindUsersByName` method has an overload that allows us to specify the page index and page size, and returns only those user accounts that fall within that range of records.

In particular, this overload has the following signature:
`FindUsersByName(usernameToMatch, pageIndex, pageSize, totalRecords)`.

The *pageIndex* parameter specifies the page of user accounts to return; *pageSize* indicates how many records to display per page. The *totalRecords* parameter is a `ByRef` parameter that returns the number of total user accounts in the user store.

> **NOTE**
> The data returned by `FindUsersByName` is sorted by username; the sort criteria cannot be customized.

The GridView can be configured to utilize custom paging, but only when bound to an ObjectDataSource control.

For the ObjectDataSource control to implement custom paging, it requires two methods: one that is passed a start row index and the maximum number of records to display, and returns the precise subset of records that fall within that span; and a method that returns the total number of records being paged through. The `FindUsersByName` overload accepts a page index and page size, and returns the total number of records through a `ByRef` parameter. So there is an interface mismatch here.

One option would be to create a proxy class that exposes the interface the ObjectDataSource expects, and then internally calls the `FindUsersByName` method. Another option - and the one we'll use for this article - is to create our own paging interface and use that instead of the GridView's built-in paging interface.

Creating a First, Previous, Next, Last Paging Interface

Let's build a paging interface with First, Previous, Next, and Last LinkButtons. The First LinkButton, when clicked, will take the user to the first page of data, whereas Previous will return him to the previous page. Likewise, Next and Last will move the user to the next and last page, respectively. Add the four LinkButton controls beneath the `UserAccounts` GridView.

```
<p>
 <asp:LinkButton ID="lnkFirst" runat="server">  First</asp:LinkButton> |
 <asp:LinkButton ID="lnkPrev" runat="server">  Prev</asp:LinkButton> |
 <asp:LinkButton ID="lnkNext" runat="server">Next  </asp:LinkButton> |
 <asp:LinkButton ID="lnkLast" runat="server">Last  </asp:LinkButton>
</p>
```

Next, create an event handler for each of the LinkButton's `Click` events.

Figure 7 shows the four LinkButtons when viewed through the Visual Web Developer Design view.

Figure 7: Add First, Previous, Next, and Last LinkButtons Beneath the GridView (Click to view full-size image)

Keeping Track of the Current Page Index

When a user first visits the `ManageUsers.aspx` page or clicks one of the filtering buttons, we want to display the first page of data in the GridView. When the user clicks one of the navigation LinkButtons, however, we need to update the page index. To maintain the page index and the number of records to display per page, add the following two properties to the page's code-behind class:

```
Private Property PageIndex() As Integer
 Get
 Dim o As Object = ViewState("PageIndex")
 If o Is Nothing Then
 Return 0
 Else
 Return Convert.ToInt32(o)
 End If
 End Get
 Set(ByVal Value As Integer)
 ViewState("PageIndex") = Value
 End Set
End Property

Private ReadOnly Property PageSize() As Integer
 Get
 Return 10
 End Get
End Property
```

Like the `UsernameToMatch` property, the `PageIndex` property persists its value to view state. The read-only `PageSize` property returns a hard-coded value, 10. I invite the interested reader to update this property to use the same pattern as `PageIndex`, and then to augment the `ManageUsers.aspx` page such that the person visiting the page can specify how many user accounts to display per page.

Retrieving Just the Current Page's Records, Updating the Page Index, and Enabling and Disabling the Paging Interface LinkButtons

With the paging interface in place and the `PageIndex` and `PageSize` properties added, we are ready to update the `BindUserAccounts` method so that it uses the appropriate `FindUsersByName` overload. Additionally, we need to have this method enable or disable the paging interface depending on what page is being displayed. When viewing the first page of data, the First and Previous links should be disabled; Next and Last should be disabled when viewing the last page.

Update the `BindUserAccounts` method with the following code:

```
Private Sub BindUserAccounts()
 Dim totalRecords As Integer
 UserAccounts.DataSource = Membership.FindUsersByName(Me.UsernameToMatch + "%", Me.PageIndex, Me.PageSize,
totalRecords)
 UserAccounts.DataBind()

 ' Enable/disable the paging interface
 Dim visitingFirstPage As Boolean = (Me.PageIndex = 0)
 lnkFirst.Enabled = Not visitingFirstPage
 lnkPrev.Enabled = Not visitingFirstPage

 Dim lastPageIndex As Integer = (totalRecords - 1) / Me.PageSize
 Dim visitingLastPage As Boolean = (Me.PageIndex >= lastPageIndex)
 lnkNext.Enabled = Not visitingLastPage
 lnkLast.Enabled = Not visitingLastPage
End Sub
```

Note that the total number of records being paged through is determined by the last parameter of the `FindUsersByName` method. After the specified page of user accounts are returned, the four LinkButtons are either enabled or disabled, depending on whether the first or last page of data is being viewed.

The last step is to write the code for the four LinkButtons' `Click` event handlers. These event handlers need to update the `PageIndex` property and then rebind the data to the GridView via a call to `BindUserAccounts` The First, Previous, and Next event handlers are very simple. The `Click` event handler for the Last LinkButton, however, is a bit more complex because we need to determine how many records are being displayed in order to determine

the last page index.

```
Protected Sub lnkFirst_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles lnkFirst.Click
 Me.PageIndex = 0
 BindUserAccounts()
End Sub

Protected Sub lnkPrev_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles lnkPrev.Click
 Me.PageIndex -= 1
 BindUserAccounts()
End Sub

Protected Sub lnkNext_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles lnkNext.Click
 Me.PageIndex += 1
 BindUserAccounts()
End Sub

Protected Sub lnkLast_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles lnkLast.Click
 ' Determine the total number of records
 Dim totalRecords As Integer
 Membership.FindUsersByName(Me.UsernameToMatch + "%", Me.PageIndex, Me.PageSize, totalRecords)
 ' Navigate to the last page index
 Me.PageIndex = (totalRecords - 1) / Me.PageSize
 BindUserAccounts()
End Sub
```

Figures 8 and 9 show the custom paging interface in action. Figure 8 shows the `ManageUsers.aspx` page when viewing the first page of data for all user accounts. Note that only 10 of the 13 accounts are displayed. Clicking the Next or Last link causes a postback, updates the `PageIndex` to 1, and binds the second page of user accounts to the grid (see Figure 9).

Figure 8: The First 10 User Accounts are Displayed (Click to view full-size image)

Figure 9: Clicking the Next Link Displays the Second Page of User Accounts (Click to view full-size image)

Summary

Administrators often need to select a user from the list of accounts. In previous tutorials we looked at using a drop-down list populated with the users, but this approach does not scale well. In this tutorial we explored a better alternative: a filterable interface whose results are displayed in a paged GridView. With this user interface, administrators can quickly and efficiently locate and select one user account among thousands.

Happy Programming!

Recovering and Changing Passwords (VB)

2/20/2020 • 20 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

ASP.NET includes two Web controls for assisting with recovering and changing passwords. The PasswordRecovery control enables a visitor to recover his lost password. The ChangePassword control allows the user to update his password. Like the other Login-related Web controls we've seen throughout this tutorial series, the PasswordRecovery and ChangePassword controls work with the Membership framework behind the scenes to reset or modify users' passwords.

Introduction

Between the websites for my bank, utility company, phone company, email accounts, and personalized web portals, I, like most people, have dozens of different passwords to remember. With so many credentials to memorize these days, it's not uncommon for people to forget their password. To account for this, websites that offer user accounts need to include a way for a user to recover his password. This process typically involves generating a new, random password and emailing it to the user's email address on file. After receiving their new password most users return to the site and change their password from the randomly generated one to a more memorable one.

ASP.NET includes two Web controls for assisting with recovering and changing passwords. The PasswordRecovery control enables a visitor to recover his lost password. The ChangePassword control allows the user to update his password. Like the other Login-related Web controls we've seen throughout this tutorial series, the PasswordRecovery and ChangePassword controls work with the Membership framework behind the scenes to reset or modify users' passwords.

In this tutorial we will examine using these two controls. We will also see how to programmatically change and reset a user's password via the `MembershipUser` class's `ChangePassword` and `ResetPassword` methods.

Step 1: Helping Users Recover Lost Passwords

All websites that support user accounts need to provide users with some mechanism for recovering their forgotten passwords. The good news is that implementing such functionality in ASP.NET is a breeze thanks to the PasswordRecovery Web control. The PasswordRecovery control renders an interface that prompts the user for their username and, if needed, the answer to their security question. It then emails the user their password.

> **NOTE**
>
> Because email messages are transmitted over the wire in plain-text there are security risks involved with sending a user's password via email.

The PasswordRecovery control consists of three views:

- **UserName** - prompts the visitor for their username. This is the initial view.
- **Question**- displays the user's username and security question as text, along with a TextBox for the user to enter the answer to his security question.
- **Success**- displays a message informing the user that his password has been emailed.

The views displayed and actions performed by the PasswordRecovery control depend upon the following Membership configuration settings:

- `RequiresQuestionAndAnswer`
- `EnablePasswordRetrieval`
- `EnablePasswordReset`

The Membership framework's `RequiresQuestionAndAnswer` setting indicates whether users must specify a security question and answer when registering for an account. As we discussed in the *Creating User Accounts* tutorial, if `RequiresQuestionAndAnswer` is True (the default) then the CreateUserWizard's interface includes TextBox controls for the new user's security question and answer; if `RequiresQuestionAndAnswer` is False, no such information is collected. Similarly, if `RequiresQuestionAndAnswer` is True, then the PasswordRecovery control displays the Question view after the user has entered their username; the password is recovered only if the user enters the correct security answer. If `RequiresQuestionAndAnswer` is False, however, the PasswordRecovery control moves straight from the UserName view to the Success view.

After the user has provided his username - or his username and security answer, if `RequiresQuestionAndAnswer` is True - the PasswordRecovery emails the user his password. If the `EnablePasswordRetrieval` option is set to True, then the user is emailed their current password. If it is set to False and `EnablePasswordReset` is set to True, then the PasswordRecovery control generates a new, random password for the user, and emails this new password to them. If both `EnablePasswordRetrieval` and `EnablePasswordReset` are False, the PasswordRecovery control throws an exception.

> **NOTE**
> Recall that the `SqlMembershipProvider` stores users' passwords in one of three formats: Clear, Hashed (the default), or Encrypted. The storage mechanism used depends on the Membership configuration settings; the demo application uses the Hashed password format. When using the Hashed password format the `EnablePasswordRetrieval` option must be set to False because the system cannot determine the user's actual password from the hashed version stored in the database.

Figure 1 illustrates how the PasswordRecovery's interface and behavior is influenced by the Membership configuration.

Figure 1: The `RequiresQuestionAndAnswer`, `EnablePasswordRetrieval`, and `EnablePasswordReset` Influence the PasswordRecovery control's Appearance and Behavior (Click to view full-size image)

> **NOTE**
>
> In the *Creating the Membership Schema in SQL Server* tutorial we configured the Membership provider by setting `RequiresQuestionAndAnswer` to True, `EnablePasswordRetrieval` to False, and `EnablePasswordReset` to True.

Using the PasswordRecovery Control

Let's look at using the PasswordRecovery control in an ASP.NET page. Open `RecoverPassword.aspx` and drag and drop a PasswordRecovery control from the Toolbox onto the Designer; set its `ID` to `RecoverPwd`. Like the Login and CreateUserWizard Web controls, the PasswordRecovery control's views render a rich composite interface that includes Labels, TextBoxes, Buttons, and validation controls. You can customize the appearance of the views through the control's style properties or by converting the views into templates. I leave this as an exercise for the interested reader.

When a user visits this page she will enter her username and click the Submit button. Because we have set the `RequiresQuestionAndAnswer` property to True in our Membership configuration settings, the PasswordRecovery control will then display the Question view. After the user enters her correct security answer and clicks Submit,

the PasswordRecovery control will update the user's password to a randomly-generated one, and email this password to the email address on file. All of this was possible without us having to write a single line of code!

Before you test this page, there's one final piece of configuration to tend to: we need to specify the mail delivery settings in `Web.config`. The PasswordRecovery control relies on these settings for sending the email.

The mail delivery configuration is specified through the `<system.net>` element's `<mailSettings>` element. Use the `<smtp>` element to indicate the delivery method and the default From address. The following markup configures mail settings to use a network SMTP server named `smtp.example.com` on port 25 and with username/password credentials of username and password.

> **NOTE**
>
> `<system.net>` is a child element of the root `<configuration>` element and a sibling of `<system.web>`. Therefore, do not put the `<system.net>` element within the `<system.web>` element; instead, put it at the same level.

```
<configuration>
 ...
 <system.net>
 <mailSettings>
 <smtp deliveryMethod="Network" from="youraddress@example.com">
 <network
 host="smtp.example.com"
 userName="username"
 password="password"
 port="25" />
 </smtp>
 </mailSettings>
 </system.net>
</configuration>
```

In addition to using an SMTP server on the network, you can alternatively specify a pickup directory where email messages to be sent should be deposited.

Once you have configured the SMTP settings, visit the `RecoverPassword.aspx` page through a browser. First try entering a username that doesn't exist in the user store. As Figure 2 shows, the PasswordRecovery control displays a message indicating that the user information could not be accessed. The text of the message can be customized through the control's `UserNameFailureText` property.

Figure 2: An Error Message is Displayed if an Invalid Username is Entered (Click to view full-size image)

Now enter a username. Use the username of an account in the system with an email address that you can access and whose security answer you know. After entering the username and clicking Submit, the PasswordRecovery control displays its Question view. As with the UserName view, if you enter an incorrect answer the PasswordRecovery control displays an error message (see Figure 3). Use the `QuestionFailureText` property to customize this error message.

Figure 3: An Error Message is Displayed if the User Enters an Invalid Security Answer (Click to view full-size image)

Finally, enter the correct security answer and click Submit. Behind the scenes, the PasswordRecovery control generates a random password, assigns it to the user account, sends an email informing the user of their new password (see Figure 4), and then displays the Success view.

Figure 4: The User is Sent an Email with His New Password (Click to view full-size image)

Customizing the Email

The default email sent by the PasswordRecovery control is rather dull (see Figure 4). The message is sent from the account specified in the `<smtp>` element's `from` attribute with the subject Password and the plain-text body:

Please return to the site and log in using the following information.

User Name: *username*

Password: *password*

This message can be customized programmatically through an event handler for the PasswordRecovery control's `SendingMail` event, or declaratively through the `MailDefinition` property. Let's explore both of these options.

The `SendingMail` event is fired right before the email message is sent and is our last chance to programmatically

adjust the email message. When this event is raised, the event handler is passed an object of type `MailMessageEventArgs`, whose `Message` property contains a reference to the email about to be sent.

Create an event handler for the `SendingMail` event and add the following code, which programmatically adds `webmaster@example.com` to the CC list.

```
Protected Sub RecoverPwd_SendingMail(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.MailMessageEventArgs)Handles RecoverPwd.SendingMail
 e.Message.CC.Add("webmaster@example.com")
End Sub
```

The email message can also be configured through declarative means. The PasswordRecovery's `MailDefinition` property is an object of type `MailDefinition`. The `MailDefinition` class offers a host of email-related properties, including `From`, `CC`, `Priority`, `Subject`, `IsBodyHtml`, `BodyFileName`, and others. For starters, set the `Subject` property to something more descriptive than the one used by default (Password), such as Your password has been reset...

To customize the body of the email message we need to create a separate email template file that contains the body's contents. Start by creating a new folder in the website named `EmailTemplates`. Next, add a new text file to this folder named `PasswordRecovery.txt` and add the following content:

```
Your password has been reset, <%UserName%>!

According to our records, you have requested that your password be reset. Your new
password is: <%Password%>

If you have any questions or trouble logging on please contact a site administrator.

Thank you!
```

Note the use of the placeholders `<%UserName%>` and `<%Password%>`. The PasswordRecovery control automatically replaces these two placeholders with the user's username and recovered password prior to sending the email.

Lastly, point the `MailDefinition`'s `BodyFileName` property to the email template we just created (`~/EmailTemplates/PasswordRecovery.txt`).

After making these changes revisit the `RecoverPassword.aspx` page and enter your username and security answer. You receive should an email that looks like the one in Figure 5. Note that `webmaster@example.com` has been CC'd and that the subject and body have been updated.

Figure 5: The Subject, Body, and CC List Have Been Updated (Click to view full-size image)

To send an HTML-formatted email set `IsBodyHtml` to True (the default is False) and update the email template to include HTML.

The `MailDefinition` property is not unique to the PasswordRecovery class. As we will see in Step 2, the ChangePassword control also offers a `MailDefinition` property. Moreover, the CreateUserWizard control includes such a property that you can configure to automatically send a welcome email message to new users.

> **NOTE**
> Currently there are no links in the left-hand navigation for reaching the `RecoverPassword.aspx` page. A user would only be interested in visiting this page if she was unable to successfully log on to the site. Therefore, update the `Login.aspx` page to include a link to the `RecoverPassword.aspx` page.

Programmatically Resetting a User's Password

When resetting a user's password the PasswordRecovery control calls the `MembershipUser` object's `ResetPassword` method. This method has two overloads:

- `ResetPassword` - resets a user's password. Use this overload if `RequiresQuestionAndAnswer` is False.
- `ResetPassword(securityAnswer)` - resets a user's password only if the supplied *securityAnswer* is correct. Use this overload if `RequiresQuestionAndAnswer` is True.

Both overloads return the new, randomly-generated password.

Like with the other methods in the Membership framework, the `ResetPassword` method delegates to the configured provider. The `SqlMembershipProvider` invokes the `aspnet_Membership_ResetPassword` stored procedure, passing in the user's username, the new password, and the supplied password answer, among other fields. The stored procedure ensures that the password answer matches and then updates the user's password.

A couple of low-level implementation notes:

- A locked out user cannot reset her password. However, an unapproved user may. We will discuss the locked out and approved states in more detail in the *Unlocking and Approving User* Accounts tutorial.
- If the password answer is incorrect, the user's failed password answer attempt count is incremented. If a specified number of invalid security answer attempts occur within a specified time window, the user is locked out.

A Word on How the Random Passwords are Generated

The randomly-generated passwords shown in the email messages in Figures 4 and 5 are created by the Membership class's `GeneratePassword` method. This method accepts two integer input paramters - *length* and *numberOfNonAlphanumericCharacters* - and returns a string at least *length* characters long with at least *numberOfNonAlphanumericCharacters* number of non-alphanumeric characters. When this method is called from within the Membership classes or Login-related Web controls, the values for these two parameters are determined by the Membership configuration's `MinRequiredPasswordLength` and `MinRequiredNonalphanumericCharacters` properties, which we set to 7 and 1, respectively.

The `GeneratePassword` method uses a cryptographically strong random number generator to ensure that there is no bias in what random characters are selected. Furthermore, `GeneratePassword` is `Public`, meaning that you can use it directly from your ASP.NET application if you need to generate random strings or passwords.

NOTE

The `SqlMembershipProvider` class always generates a random password at least 14 characters long, so if `MinRequiredPasswordLength` is less than 14 then its value is ignored.

Step 2: Changing Passwords

The randomly-generated passwords are difficult to remember. Consider the password shown in Figure 4: `WWGUZv(f2yM:Bd`. Try committing that to memory! Needless to say, after a user is sent a randomly-generated password of this sort, she'll want to change the password to something more memorable.

Use the ChangePassword control to create an interface for a user to change her password. Much like the PasswordRecovery control, the ChangePassword control consists of two views: Change Password and Success. The Change Password view prompts the user for their old and new passwords. Upon supplying the correct old password and a new password that meets the minimum length and non-alphanumeric character requirements, the ChangePassword control updates the user's password and displays the Success view.

NOTE

The ChangePassword control modifies the user's password by invoking the `MembershipUser` object's `ChangePassword` method. The ChangePassword method accepts two `String` input parameters - *oldPassword* and *newPassword*- and updates the user's account with the *newPassword*, assuming the supplied *oldPassword* is correct.

Open the `ChangePassword.aspx` page and add a ChangePassword control to the page, naming it `ChangePwd`. At this point, the Design view should show the Change Password view (see Figure 6). Like with the PasswordRecovery control, you can toggle between the views via the control's Smart Tag. Furthermore, these views' appearances are customizable through the assorted style properties or by converting them to a template.

Figure 6: Add a ChangePassword Control to the Page (Click to view full-size image)

The ChangePassword control can update the currently logged in user's password *or* the password of another, specified user. As Figure 6 shows, the default Change Password view renders just three TextBox controls: one for the old password and two for the new password. This default interface is used to update the currently logged on user's password.

To use the ChangePassword control to update another user's password, set the control's `DisplayUserName` property to True. Doing so adds a fourth TextBox to the page, prompting for the username of the user whose password to change.

Setting `DisplayUserName` to True is useful if you want to let a logged out user change her password without having to log in. Personally, I think there's nothing wrong with requiring a user to login before allowing her to change her password. Therefore, leave `DisplayUserName` set to False (its default). In making this decision, however, we essentially are barring anonymous users from reaching this page. Update the site's URL authorization rules so as to deny anonymous users from visiting `ChangePassword.aspx`. If you need to refresh your memory on the URL authorization rule syntax, refer back to the *User-Based Authorization* tutorial.

> **NOTE**
>
> It may seem that the `DisplayUserName` property is useful for allowing administrators to change other users' passwords. However, even when `DisplayUserName` is set to True the correct old password must be known and entered. We will talk about techniques for allowing administrators to change users' passwords in Step 3.

Visit the `ChangePassword.aspx` page through a browser and change your password. Note that an error message is displayed if you enter a new password that fails to meet the password length and non-alphanumeric character requirements specified in the Membership configuration (see Figure 7).

Figure 7: Add a ChangePassword Control to the Page (Click to view full-size image)

Upon entering the correct old password and a valid new password, the logged on user's password is changed and the Success view displayed.

Sending a Confirmation Email

By default, the ChangePassword control does not send an email message to the user whose password was just updated. If you'd like to send an email, simply configure the control's `MailDefinition` property. Let's configure the ChangePassword control so that the user is sent an HTML-formatted email that contains their new password.

Start by creating a new file in the `EmailTemplates` folder named `ChangePassword.htm`. Add the following markup:

```
<html>
 <body>
 <h2>Your Password Has Been Changed!</h2>
 <p>
 This email confirms that your password has been changed.
 </p>
 <p>
 To log on to the site, use the following credentials:
 </p>
 <table>
 <tr>
 <td>
 <b>Username:</b>
 </td>
 <td>
 <%UserName%>
 </td>
 </tr>
 <tr>
 <td>
 <b>Password:</b>
 </td>
 <td>
 <%Password%>
 </td>
 </tr>
 </table>
 <p>
 If you have any questions or encounter any problems logging in,
 please contact a site administrator.
 </p>
 </body>
</html>
```

Next, set the ChangePassword control's `MailDefinition` property's `BodyFileName`, `IsBodyHtml`, and `Subject` properties to ~/EmailTemplates/ChangePassword.htm, True, and Your password has changed!, respectively.

After making these changes, revisit the page and change your password again. This time, the ChangePassword control sends a customized, HTML-formatted email to the user's email address on file (see Figure 8).

Figure 8: An Email Message Informs the User That Their Password has Changed (Click to view full-size image)

Step 3: Allowing Administrators to Change Users' Passwords

A common feature in applications that support user accounts is the ability for an administrative user to change other users' passwords. Sometimes this functionality is required because the system lacks the ability for users to change their own passwords. In such a case, the only way for a user to recover their forgotten password would be for the administrator to assign them a new password. With the PasswordRecovery and ChangePassword controls, however, administrative users need not busy themselves with changing users' passwords, as users are capable of doing this themselves.

But what if your client insists that administrative users should be able to change other users' passwords? Unfortunately, adding this functionality can be a bit of work. To change a user's password, both the old and new password must be supplied to the `MembershipUser` object's `ChangePassword` method, but an administrator shouldn't have to know a user's password in order to modify it.

One workaround is to first reset the user's password and then change it to the new password using code like the following:

```
Dim usr As MembershipUser = Membership.GetUser(username)
Dim resetPwd As String = usr.ResetPassword()
usr.ChangePassword(resetPwd, newPassword)
```

This code starts by retrieving information about *username*, which is the user whose password the administrator wishes to change. Next, the `ResetPassword` method is invoked, which assigns and the user a new, random password. This randomly-generated password is returned by the method and stored in the variable `resetPwd`. Now that we know the user's password, we can change it via a call to `ChangePassword`.

The problem is that this code only works if the Membership system configuration is set such that `RequiresQuestionAndAnswer` is False. If `RequiresQuestionAndAnswer` is True, as it is with our application, then the `ResetPassword` method needs to be passed the security answer, otherwise it will throw an exception.

If the Membership framework is configured to require a security question and answer, and yet your client insists that administrators be able to change users' passwords, you have three options:

- Throw your hands in the air and tell your client that this is just one thing that cannot be done.
- Set `RequiresQuestionAndAnswer` to False. This results in a less secure application. Imagine that a nefarious user has gained access to another user's email inbox. Perhaps the compromised user has left their desk to go to lunch and didn't lock their workstation, or maybe they accessed their email from a public terminal and didn't sign out. In either case, the nefarious user can visit the `RecoverPassword.aspx` page and enter the user's username. The system will then email the recovered password without prompting for the security answer.
- Bypass the abstraction layer created by the Membership framework and work directly with the SQL Server database. The Membership schema includes a stored procedure named `aspnet_Membership_SetPassword` that sets a user's password and does not require the security answer or old password in order to accomplish its task.

None of these options are particularly appealing, but that's how the life of a developer goes sometimes.

I went ahead and implemented the third approach, writing code that bypasses the `Membership` and `MembershipUser` classes and operates directly against the `SecurityTutorials` database.

NOTE

By working directly with the database, the encapsulation provided by the Membership framework is shattered. This decision ties us to the `SqlMembershipProvider`, making our code less portable. Furthermore, this code may not work as expected in future versions of ASP.NET if the Membership schema changes. This approach is a workaround and, like most workarounds, is not an example of best practices.

The code has some unattractive bits and is quite lengthy. Therefore, I don't want to clutter this tutorial with an in-depth examination of it. If you are interested in learning more, download the code for this tutorial and visit the `~/Administration/ManageUsers.aspx` page. This page, which we created in the preceding tutorial, lists each user. I've updated the GridView to include a link to the `UserInformation.aspx` page, passing the selected user's username through the querystring. The `UserInformation.aspx` page displays information about the selected user and TextBoxes for changing their password (see Figure 9).

After entering the new password, confirming it in the second TextBox, and clicking the Update User Button, a postback ensues and the `aspnet_Membership_SetPassword` stored procedure is invoked, updating the user's password. I encourage those readers interested in this functionality to become more familiar with the code and try extending the functionality to include sending an email to the user whose password was changed.

Figure 9: An Administrator May Change a User's Password (Click to view full-size image)

NOTE

The `UserInformation.aspx` page currently only works if the Membership framework is configured to store passwords in Clear or Hashed format. It lacks the code to encrypt the new password, although you are invited to add this functionality. The way I recommend adding the necessary code is to use a decompiler like Reflector to examine the source code for methods in the .NET Framework; start by examining the `SqlMembershipProvider` class's `ChangePassword` method. This is the technique I used to write the code for creating a hash of the password.

Summary

ASP.NET offers two controls to help users manage their password. The PasswordRecovery control is useful for those who have forgotten their passwords. Depending on the Membership framework's configuration, the user is either emailed their existing password or a new, randomly-generated password. The ChangePassword control enables a user to update their password.

Like the Login and CreateUserWizard controls, the PasswordRecovery and ChangePassword controls render a rich

user interface without having to write a lick of declarative markup or line of code. If the default user interface doesn't meet your needs, you can customize it through a variety of style properties. Alternatively, the controls' interfaces may be converted into templates, for an even finer degree of control. Behind the scenes these controls use the Membership API, invoking the `MembershipUser` object's `ResetPassword` and `ChangePassword` methods.

Happy Programming!

Unlocking and Approving User Accounts (VB)

2/20/2020 • 17 minutes to read • Edit Online

by Scott Mitchell

Download Code or Download PDF

> This tutorial shows how to build a web page for administrators to manage users' locked out and approved statuses. We will also see how to approve new users only after they have verified their email address.

Introduction

Along with a username, password, and email, each user account has two status fields that dictate whether the user can log into the site: locked out and approved. A user is automatically locked out if they provide invalid credentials a specified number of times within a specified number of minutes (the default settings lock a user out after 5 invalid login attempts within 10 minutes). The approved status is useful in scenarios where some action must transpire before a new user is able to log on to the site. For example, a user might need to first verify their email address or be approved by an administrator before being able to login.

Because a locked out or unapproved user cannot login, it's only natural to wonder how these statuses can be reset. ASP.NET does not include any built-in functionality or Web controls for managing users' locked out and approved statuses, in part because these decisions need to be handled on a site-by-site basis. Some sites might automatically approve all new user accounts (the default behavior). Others have an administrator approve new accounts or do not approve users until they visit a link sent to the email address provided when they signed up. Likewise, some sites may lock out users until an administrator resets their status, while other sites send an email to the locked out user with a URL they can visit to unlock their account.

This tutorial shows how to build a web page for administrators to manage users' locked out and approved statuses. We will also see how to approve new users only after they have verified their email address.

Step 1: Managing Users' Locked Out and Approved Statuses

In the *Building an Interface to Select One User Account from Many* tutorial we constructed a page that listed each user account in a paged, filtered GridView. The grid lists each user's name and email, their approved and locked out statuses, whether they're currently online, and any comments about the user. To manage users' approved and locked out statuses, we could make this grid editable. To change a user's approved status, the administrator would first locate the user account and then edit the corresponding GridView row, checking or unchecking the approved checkbox. Alternatively, we could manage the approved and locked out statuses through a separate ASP.NET page.

For this tutorial let's use two ASP.NET pages: `ManageUsers.aspx` and `UserInformation.aspx`. The idea here is that `ManageUsers.aspx` lists the user accounts in the system, while `UserInformation.aspx` enables the administrator to manage the approved and locked out statuses for a specific user. Our first order of business is to augment the GridView in `ManageUsers.aspx` to include a HyperLinkField, which renders as a column of links. We want each link to point to `UserInformation.aspx?user=UserName`, where *UserName* is the name of the user to edit.

> **NOTE**
>
> If you downloaded the code for the *Recovering and Changing Passwords* tutorial you may have noticed that the `ManageUsers.aspx` page already contains a set of "Manage" links and the `UserInformation.aspx` page provides an interface for changing the selected user's password. I decided not to replicate that functionality in the code associated with this tutorial because it worked by circumventing the Membership API and operating directly with the SQL Server database to change a user's password. This tutorial starts from scratch with the `UserInformation.aspx` page.

Adding "Manage" Links to the `UserAccounts` GridView

Open the `ManageUsers.aspx` page and add a HyperLinkField to the `UserAccounts` GridView. Set the HyperLinkField's `Text` property to "Manage" and its `DataNavigateUrlFields` and `DataNavigateUrlFormatString` properties to `UserName` and "UserInformation.aspx?user={0}", respectively. These settings configure the HyperLinkField such that all of the hyperlinks display the text "Manage", but each link passes in the appropriate *UserName* value into the querystring.

After adding the HyperLinkField to the GridView, take a moment to view the `ManageUsers.aspx` page through a browser. As Figure 1 shows, each GridView row now includes a "Manage" link. The "Manage" link for Bruce points to `UserInformation.aspx?user=Bruce`, whereas the "Manage" link for Dave points to `UserInformation.aspx?user=Dave`.

Figure 1: The HyperLinkField Adds a "Manage" Link for Each User Account (Click to view full-size image)

We will create the user interface and code for the `UserInformation.aspx` page in a moment, but first let's talk about how to programmatically change a user's locked out and approved statuses. The `MembershipUser` class has `IsLockedOut` and `IsApproved` properties. The `IsLockedOut` property is read-only. There is no mechanism to programmatically lock out a user; to unlock a user, use the `MembershipUser` class's `UnlockUser` method. The `IsApproved` property is readable and writeable. To save any changes to this property, we need to call the `Membership` class's `UpdateUser` method, passing in the modified `MembershipUser` object.

Because the `IsApproved` property is readable and writeable, a CheckBox control is probably the best user interface element for configuring this property. However, a CheckBox will not work for the `IsLockedOut` property because an administrator cannot lock out a user, she may only unlock a user. A suitable user interface for the `IsLockedOut` property is a Button that, when clicked, unlocks the user account. This Button should only be enabled if the user is locked out.

Creating the `UserInformation.aspx` Page

We are now ready to implement the user interface in `UserInformation.aspx`. Open this page and add the

following Web controls:

- A HyperLink control that, when clicked, returns the administrator to the `ManageUsers.aspx` page.
- A Label Web control for displaying the selected user's name. Set this Label's `ID` to `UserNameLabel` and clear out its Text property.
- A CheckBox control named `IsApproved`. Set its `AutoPostBack` property to `True`.
- A Label control for displaying the user's last locked out date. Name this Label `LastLockedOutDateLabel` and clear out its `Text` property.
- A Button for unlocking the user. Name this Button `UnlockUserButton` and set its `Text` property to "Unlock User".
- A Label control for displaying status messages, such as, "The user's approved status has been updated." Name this control `StatusMessage`, clear out its `Text` property, and set its `CssClass` property to `Important`. (The `Important` CSS class is defined in the `Styles.css` stylesheet file; it displays the corresponding text in a large, red font.)

After adding these controls, the Design view in Visual Studio should look similar to the screen shot in Figure 2.

Figure 2: Create the User Interface for `UserInformation.aspx` (Click to view full-size image)

With the user interface complete, our next task is to set the `IsApproved` CheckBox and other controls based on the selected user's information. Create an event handler for the page's `Load` event and add the following code:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
     If Not Page.IsPostBack Then
          ' If querystring value is missing, send the user to ManageUsers.aspx
          Dim userName As String = Request.QueryString("user")
          If String.IsNullOrEmpty(userName) Then
               Response.Redirect("ManageUsers.aspx")
          End If

          ' Get information about this user
          Dim usr As MembershipUser = Membership.GetUser(userName)
          If usr Is Nothing Then
               Response.Redirect("ManageUsers.aspx")

          End If

          UserNameLabel.Text = usr.UserName
          IsApproved.Checked = usr.IsApproved

          If usr.LastLockoutDate.Year < 2000 Then
               LastLockoutDateLabel.Text = String.Empty
          Else
               LastLockoutDateLabel.Text = usr.LastLockoutDate.ToShortDateString()
               UnlockUserButton.Enabled = usr.IsLockedOut
          End If
     End If
End Sub
```

The above code starts by ensuring that this is the first visit to the page and not a subsequent postback. It then reads the username passed through the `user` querystring field and retrieves information about that user account via the `Membership.GetUser(username)` method. If no username was supplied through the querystring, or if the specified user could not be found, the administrator is sent back to the `ManageUsers.aspx` page.

The `MembershipUser` object's `UserName` value is then displayed in the `UserNameLabel` and the `IsApproved` CheckBox is checked based on the `IsApproved` property value.

The `MembershipUser` object's `LastLockoutDate` property returns a `DateTime` value indicating when the user was last locked out. If the user has never been locked out, the value returned depends on the Membership provider. When a new account is created, the `SqlMembershipProvider` sets the `aspnet_Membership` table's `LastLockoutDate` field to `1754-01-01 12:00:00 AM`. The above code displays an empty string in the `LastLockoutDateLabel` if the `LastLockoutDate` property occurs before year 2000; otherwise, the date portion of the `LastLockoutDate` property is displayed in the Label. The `UnlockUserButton`'s `Enabled` property is set to the user's locked out status, meaning that this Button will only be enabled if the user is locked out.

Take a moment to test the `UserInformation.aspx` page through a browser. You will, of course, need to start at `ManageUsers.aspx` and select a user account to manage. Upon arriving at `UserInformation.aspx`, note that the `IsApproved` CheckBox is only checked if the user is approved. If the user has ever been locked out, their last locked out date is displayed. The Unlock User button is enabled only if the user is currently locked out. Checking or unchecking the `IsApproved` CheckBox or clicking the Unlock User button causes a postback, but no modifications are made to the user account because we've yet to create event handlers for these events.

Return to Visual Studio and create event handlers for the `IsApproved` CheckBox's `CheckedChanged` event and the `UnlockUser` Button's `Click` event. In the `CheckedChanged` event handler, set the user's `IsApproved` property to the `Checked` property of the CheckBox and then save the changes via a call to `Membership.UpdateUser`. In the `Click` event handler, simply call the `MembershipUser` object's `UnlockUser` method. In both event handlers, display a suitable message in the `StatusMessage` Label.

```
Protected Sub IsApproved_CheckedChanged(ByVal sender As Object, ByVal e As System.EventArgs) Handles
IsApproved.CheckedChanged
     'Toggle the user's approved status
     Dim userName As String = Request.QueryString("user")
     Dim usr As MembershipUser = Membership.GetUser(userName)
     usr.IsApproved = IsApproved.Checked
     Membership.UpdateUser(usr)

     StatusMessage.Text = "The user's approved status has been updated."

End Sub

Protected Sub UnlockUserButton_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles
UnlockUserButton.Click
     'Unlock the user account
     Dim userName As String = Request.QueryString("user")
     Dim usr As MembershipUser = Membership.GetUser(userName)
     usr.UnlockUser()
     UnlockUserButton.Enabled = False

     StatusMessage.Text = "The user account has been unlocked."
End Sub
```

Testing the `UserInformation.aspx` Page

With these event handlers in place, revisit the page and unapproved a user. As Figure 3 shows, you should see a brief message on the page indicating that the user's `IsApproved` property was successfully modified.

Figure 3: Chris has been Unapproved (Click to view full-size image)

Next, logout and try to login as the user whose account was just unapproved. Because the user is not approved, they cannot login. By default, the Login control displays the same message if the user cannot login, regardless of the reason. But in the *Validating User Credentials Against the Membership User Store* tutorial we looked at enhancing the Login control to display a more appropriate message. As Figure 4 shows, Chris is shown a message explaining that he cannot login because his account is not yet approved.

Figure 4: Chris Cannot Login Because His Account is Unapproved (Click to view full-size image)

To test the locked out functionality, attempt to login as an approved user, but use an incorrect password. Repeat this process the necessary number of times until the user's account has been locked out. The Login control was also updated to show a custom message if attempting to login from a locked out account. You know that an account has been locked out once you start seeing the following message at the login page: "Your account has been locked out because of too many invalid login attempts. Please contact the administrator to have your account unlocked."

Return to the `ManageUsers.aspx` page and click the Manage link for the locked out user. As Figure 5 shows, you should see a value in the `LastLockedOutDateLabel` the Unlock User button should be enabled. Click the Unlock User button to unlock the user account. Once you have unlocked the user, they will be able to login again.

Figure 5: Dave Has Been Locked Out of the System (Click to view full-size image)

Step 2: Specifying New Users' Approved Status

The approved status is useful in scenarios where you want some action to be performed before a new user is able

to login and access the user-specific features of the site. For example, you may be running a private website where all pages, except for the login and signup pages, are accessible only to authenticated users. But what happens if a stranger reaches your website, finds the signup page, and creates an account? To prevent this from happening you could move the signup page to an `Administration` folder, and require that an administrator manually create each account. Alternatively, you could allow anyone to signup, but prohibit site access until an administrator approves the user account.

By default, the CreateUserWizard control approves new accounts. You can configure this behavior using the control's `DisableCreatedUser` property. Set this property to `True` to not approve new user accounts.

> **NOTE**
> By default the CreateUserWizard control automatically logs on the new user account. This behavior is dictated by the control's `LoginCreatedUser` property. Because unapproved users cannot login to the site, when `DisableCreatedUser` is `True` the new user account is not logged into the site, regardless of the value of the `LoginCreatedUser` property.

If you are programmatically creating new user accounts via the `Membership.CreateUser` method, to create an unapproved user account use one of the overloads that accept the new user's `IsApproved` property value as an input parameter.

Step 3: Approving Users By Verifying their Email Address

Many websites that support user accounts do not approve new users until they verify the email address they supplied when registering. This verification process is commonly used to thwart bots, spammers, and other ne'er-do-wells as it requires a unique, verified email address and adds an extra step in the signup process. With this model, when a new user signs up they are sent an email message that includes a link to a verification page. By visiting the link the user has proven that they received the email and, therefore, that the email address provided is valid. The verification page is responsible for approving the user. This may happen automatically, thereby approving any user who reaches this page, or only after the user provides some additional information, such as a CAPTCHA.

To accommodate this workflow, we need to first update the account creation page so that new users are unapproved. Open the `EnhancedCreateUserWizard.aspx` page in the `Membership` folder and set the CreateUserWizard control's `DisableCreatedUser` property to `True`.

Next, we need to configure the CreateUserWizard control to send an email to the new user with instructions on how to verify their account. In particular, we will include a link in the email to the `Verification.aspx` page (which we've yet to create), passing in the new user's `UserId` through the querystring. The `Verification.aspx` page will lookup the specified user and mark them approved.

Sending a Verification Email to New Users

To send an email from the CreateUserWizard control, configure its `MailDefinition` property appropriately. As discussed in the previous tutorial, the ChangePassword and PasswordRecovery controls include a `MailDefinition` property that works in the same manner as the CreateUserWizard control's.

> **NOTE**
> To use the `MailDefinition` property you need to specify mail delivery options in `Web.config`. For more information, refer to Sending Email in ASP.NET.

Start by creating a new email template named `CreateUserWizard.txt` in the `EmailTemplates` folder. Use the following text for the template:

```
Hello <%UserName%>! Welcome aboard.

Your new account is almost ready, but before you can login you must first visit:
<%VerificationUrl%>

Once you have visited the verification URL you will be redirected to the login page.

If you have any problems or questions, please reply to this email.

Thanks!
```

Set the `MailDefinition`'s `BodyFileName` property to "~/EmailTemplates/CreateUserWizard.txt" and its `Subject` property to "Welcome to My Website! Please activate your account."

Note that the `CreateUserWizard.txt` email template includes a `<%VerificationUrl%>` placeholder. This is where the URL for the `Verification.aspx` page will be placed. The CreateUserWizard automatically replaces the `<%UserName%>` and `<%Password%>` placeholders with the new account's username and password, but there is no built-in `<%VerificationUrl%>` placeholder. We need to manually replace it with the appropriate verification URL.

To accomplish this, create an event handler for the CreateUserWizard's `SendingMail` event and add the following code:

```
Protected Sub NewUserWizard_SendingMail(ByVal sender As Object, ByVal e As
System.Web.UI.WebControls.MailMessageEventArgs) Handles NewUserWizard.SendingMail
     'Get the UserId of the just-added user
     Dim newUser As MembershipUser = Membership.GetUser(NewUserWizard.UserName)
     Dim newUserId As Guid = CType(newUser.ProviderUserKey, Guid)

     ' Determine the full verification URL (i.e., http://yoursite.com/Verification.aspx?ID=...)
     Dim urlBase As String = Request.Url.GetLeftPart(UriPartial.Authority) & Request.ApplicationPath
     Dim verifyUrl As String = "/Verification.aspx?ID=" + newUserId.ToString()
     Dim fullUrl As String = urlBase & verifyUrl

     ' Replace <%VerificationUrl%> with the appropriate URL and querystring

     e.Message.Body = e.Message.Body.Replace("<%VerificationUrl%>", fullUrl)
End Sub
```

The `SendingMail` event fires after the `CreatedUser` event, meaning that by the time the above event handler executes the new user account has already been created. We can access the new user's `UserId` value by calling the `Membership.GetUser` method, passing in the `UserName` entered into the CreateUserWizard control. Next, the verification URL is formed. The statement `Request.Url.GetLeftPart(UriPartial.Authority)` returns the `http://yourserver.com` portion of the URL; `Request.ApplicationPath` returns path where the application is rooted. The verification URL is then defined as `Verification.aspx?ID=userId`. These two strings are then concatenated to form the complete URL. Finally, the email message body (`e.Message.Body`) has all occurrences of `<%VerificationUrl%>` replaced with the full URL.

The net effect is that new users are unapproved, meaning that they cannot log into the site. Furthermore, they are automatically sent an email with a link to the verification URL (see Figure 6).

Figure 6: The New User Receives an Email with a Link to the Verification URL (Click to view full-size image)

> **NOTE**
>
> The CreateUserWizard control's default CreateUserWizard step displays a message informing the user their account has been created and displays a Continue button. Clicking this takes the user to the URL specified by the control's `ContinueDestinationPageUrl` property. The CreateUserWizard in `EnhancedCreateUserWizard.aspx` is configured to send new users to the `~/Membership/AdditionalUserInfo.aspx`, which prompts the user for their hometown, homepage URL, and signature. Because this information can only be added by logged on users, it makes sense to update this property to send users back to the site's homepage (`~/Default.aspx`). Moreover, the `EnhancedCreateUserWizard.aspx` page or the CreateUserWizard step should be augmented to inform the user that they have been sent a verification email and their account won't be activated until they follow the instructions in this email. I leave these modifications as an exercise for the reader.

Creating the Verification Page

Our final task is to create the `Verification.aspx` page. Add this page to the root folder, associating it with the `Site.master` master page. As we've done with most of the previous content pages added to the site, remove the Content control that references the `LoginContent` ContentPlaceHolder so that the content page uses the master page's default content.

Add a Label Web control to the `Verification.aspx` page, set its `ID` to `StatusMessage` and clear out its text property. Next, create the `Page_Load` event handler and add the following code:

```
Protected Sub Page_Load(ByVal sender As Object, ByVal e As System.EventArgs) Handles Me.Load
     If String.IsNullOrEmpty(Request.QueryString("ID")) Then
          StatusMessage.Text = "The UserId was not included in the querystring..."
     Else
          Dim userId As Guid
          Try
               userId = New Guid(Request.QueryString("ID"))
          Catch
               StatusMessage.Text = "The UserId passed into the querystring is not in the proper format..."

               Exit Sub
          End Try

          Dim usr As MembershipUser = Membership.GetUser(userId)
          If usr Is Nothing Then
               StatusMessage.Text = "User account could not be found..."
          Else
               ' Approve the user
               usr.IsApproved = True
               Membership.UpdateUser(usr)
               StatusMessage.Text = "Your account has been approved. Please <a href=""Login.aspx"">login</a>
to the site."

          End If
     End If
End Sub
```

The bulk of the above code verifies that the UserId supplied through the querystring exists, that it is a valid `Guid` value, and that it references an existing user account. If all of these checks pass, the user account is approved; otherwise, a suitable status message is displayed.

Figure 7 shows the `Verification.aspx` page when visited through a browser.

Figure 7: The New User's Account is Now Approved (Click to view full-size image)

Summary

All Membership user accounts have two statuses that determine whether the user can log into the site: `IsLockedOut` and `IsApproved`. Both of these properties must be `True` for the user to login.

The user's locked out status is used as a security measure to reduce the likelihood of a hacker breaking into a site through brute force methods. Specifically, a user is locked out if there are a certain number of invalid login attempts within a certain window of time. These bounds are configurable through the Membership provider settings in `Web.config`.

The approved status is commonly used as a means to prohibit new users from logging in until some action has

transpired. Perhaps the site requires that new accounts first be approved by the administrator or, as we saw in Step 3, by verifying their email address.

Happy Programming!

Improvements in Visual Studio 2005

4/10/2020 • 21 minutes to read • Edit Online

by Microsoft

> Visual Studio 2005 provides Web application developers with a long list of improvements and enhancements to Web projects.

Visual Studio 2005 provides Web application developers with a long list of improvements and enhancements to Web projects. As powerful as Visual Studio .NET 2002 and 2003 are, there were many complaints in the way that Web projects were handled. Visual Studio 2005 adds a significant number of new features in order to address these complaints. For those who prefer the way that Visual Studio .NET 2003 handled compilation of Web applications, see Web Application Projects.

In this module, well cover improvements in Web project creation, management, and development. In a later module, well cover improvements in building Web projects and deploying them.

FrontPage Server Extensions

Visual Studio .NET 2002 and 2003 required FrontPage Server Extensions on the box in order to create or build Web projects. Developers did have a choice between two different access modes (FrontPage Server Extensions or File access mode), both used FrontPage Server Extensions to perform tasks such as setting the application root in IIS, etc.

Visual Studio 2005 removes the reliance on FrontPage Server Extensions for local projects. Visual Studio 2005 now accesses the IIS metabase directly instead of using the FrontPage Server Extensions. Visual Studio 2005 also adds support for FTP which allows for remote project access without requiring FrontPage Server Extensions.

For those developers who want to use FrontPage Server Extensions in their projects, the option is still available. However, based upon strong feedback from the ASP.NET developer community, it is not a requirement.

> **NOTE**
>
> FrontPage Server Extensions are still required for remote project creation, opening, etc.

ASP.NET Development Server

Visual Studio 2005 ships with a new Web server called ASP.NET Development Server. (This Web server was previously known as Cassini.)

There are several benefits of the ASP.NET Development Server.

- It is now possible for non-Administrators to develop and debug against a Web server.
- The ASP.NET Development Server dynamically maps virtual directories to any location in the file system allowing for flexible project locations.
- Users on Windows XP Professional who are already using IIS will now be able to create new Web applications that will not affect the file or folder structure of their Default Web Site in IIS.

No special configuration is required to take advantage of the ASP.NET Development Server. When a Web project that is hosted on the file system is debugged or browsed, Visual Studio 2005 will automatically start an instance of the ASP.NET Development Server on a random port to service the request.

More information will be covered on the ASP.NET Development Server later in this module.

Improved File Management

In Visual Studio 2002 and 2003, a project file (.vbproj for VB.NET and .csproj for C#) stored information on all files in the Web application. The Solution Explorer display is based upon the file information in the project file. Because of this, the Solution Explorer would often display inaccurate information in cases where external editors were used. Visual Studio 2002 and 2003 would often overwrite file changes or not display the most recent version of files.

Visual Studio 2005 does away with the project file. Instead, it reads the file and folder information directly from the disk, resulting in an accurate display of the files in your project. Because the References folder in Visual Studio 2002 and 2003 does not represent an actual folder in your Web application, Visual Studio 2005 also removes the References folder from Solution Explorer. To access the references for your project in Visual Studio 2005, you should use the Property pages for the project.

Creating Web Projects

Web developers have many new options available for project creation in Visual Studio 2005. Web sites can now be created anywhere in the file system and can then be debugged or browsed using the new ASP.NET Development Server. Developers can also create new Web sites using FTP.

Click here to view a video walkthrough of creating Web projects in Visual Studio 2005.

Open Full-Screen Video

File System Projects

As you saw in the video walkthrough, you can choose to create Web sites on the file system either on the local machine or on a remote location via a file share. Web sites that are created on the file system are browsed and debugged using the ASP.NET Development Server.

> **NOTE**
>
> The ASP.NET Development Server may cause some confusion for customers. If a Web project is created on the file system in IISs directory structure (i.e. c:/inetpub/wwwroot), the Web site will still be browsed via the ASP.NET Development Server when launched from within Visual Studio 2005. Therefore, any IIS configuration (i.e. authentication methods) is not applicable.

The default web project also removes a lot of the overhead by only includes a Default.aspx page, default.cs file, and an App/_Data folder. The web.config and special folders (i.e. app/_code) are added as they are needed. Your web project only includes the files and folders that you need.

HTTP Projects

HTTP projects can either be projects that are created on a local IIS Web site or on a remote Web site. The default project location is `http://localhost`. If you click the Browse button, there are two HTTP options: Local IIS and

Remote Site. The main difference in these two options is the method in which the web site information is displayed in the Choose Location dialog and in how the files are copied to the Web server.

The Local IIS option reads the site information from the metabase on the local machine and files are copied using the file system. The Remote Site option uses the FrontPage Server Extensions and the site information and files are copied using HTTP and FrontPage Server Extensions RPC calls.

> **NOTE**
>
> The vs###/_tmp.htm file and get/_aspx/_ver.aspx are no longer used to determine version information.

The default HTTP option is Local IIS. This option reads the IIS Metabase to determine which sites are available and the location in which to create content. You can select a different folder or virtual directory by selecting it in the tree view. You can also create a new virtual directory, mark folders as applications, as well as delete existing virtual directories from this dialog box.

Figure 1: The Choose Location Dialog

Unlike in earlier versions of Visual Studio, if you check the **Use Secure Sockets Layer** checkbox and the SSL certificate does not match the URL you are browsing, you will be presented with a Security Alert dialog asking you if you would like to proceed. Using Visual Studio .NET 2003, if the certificate was not a matching one, creating the project would fail.

Figure 2: Security Alert Regarding SSL Certificate

Note on Host Headers

If you are creating a Web application on a site bound to a specific IP, you will need to ensure that a host header is configured. Otherwise, Visual Studio will create the site at `http://localhost`, but the IP address will not resolve correctly when the site is browsed or debugged from within the IDE.

If you select the Remote Site option, the dialog changes to allow you to enter the destination URL for the new Web site. This URL must be on a server that has the FrontPage Server Extensions enabled. If you want to work with your local Web server using the FrontPage Server Extensions, you can use the Remote Site option and specify a local URL.

Figure 3: Creating a Web Site on a Remote Server

When creating an application on a remote site via SSL, if the SSL certificate does not match, the confirmation dialog is slightly different than the dialog displayed when using the Local IIS option.

Figure 4: The Remote Site Security Alert

FTP

Visual Studio 2005 introduces the option to create Web sites via FTP. When you use this option, the IDE creates the files locally in the users temp folder and then uses FTP to move the files to the FTP location.

> **NOTE**
>
> The temp folder location is c:/Documents and Settings/<User>/Local Settings/Temp/VWDWebCache/<Server>/_<application name>

When using the FTP option, you will be presented with a Choose Location dialog. You enter the required FTP connection information into this dialog as shown below.

Figure 5: The Choose Location Dialog for FTP

Lab: Setup FTP site and create a project

The following steps configure the FTP site so that a user has a location that only they can upload to via FTP.

Install the FTP Service

1. Open Add Remove Programs, select Add/Remove Windows Components
2. Select Internet Information Services (Application Server on Windows 2003) and click **Details**.
3. Check **File Transfer Protocol (FTP) Service** and click **OK**.

4. Click **Next** to install the FTP service.

Create a New Folder for Content

1. In Windows Explorer, create a new folder called **User1** inside of c:/inetpub/wwwroot.

Configure folders and permissions on folders.

1. Open the Internet Information Services snap-in from Administrative Tools. You will now have an FTP Sites folder under the computer name node.
2. Expand **FTP Sites**.
3. Right-click the **Default FTP Site**, select **New**, then **Virtual Directory**, then click **Next**.
4. Enter **User1** for the virtual directory name and click **Next**.
5. Enter **c:/inetpub/wwwroot/User1** for the path and click **Next**.
6. Click **Next** and then **Finish** to complete the wizard.
7. Right-click the **User1** virtual directory under Default FTP Site and select **Properties**.
8. Check the **Write** checkbox and click **OK** to close the dialog.
9. Right-click **Default FTP Site** and select **Properties**.
10. On the **Security Accounts** tab, uncheck **Allow Anonymous Connections**.
11. Click **Yes** in the dialog asking if you want to continue.
12. Click **OK** to close the dialog.
13. Expand the **Default Web Site** under the **Web Sites** node.
14. Right-click the **User1** directory and select **Properties**
15. In the **Application Settings** section, click **Create** to mark the folder as an application.
16. Click **OK** to close the dialog.
17. Close the Internet Information Services snap-in.

Create web project

1. Open Visual Studio 2005.
2. From the **File** menu, select **New Web Site**.
3. In the **Location** dropdown, select **FTP**.
4. Click **Browse**.
5. Enter **localhost** in the **Server** textbox.
6. Enter **User1** in the Directory textbox.
7. Click **Open**. The FTP location will be entered into the New Web Site dialog.
8. Click **OK**.
9. Uncheck **Anonymous log on** in the FTP Log On dialog, enter your credentials, and click **OK**.
10. What is the URL for the project? (The URL for the project will be displayed in Solution Explorer.)
11. From the **Build** menu, select **Build Web Site** or **Build Solution**.
12. Right-click on Default.aspx in Solution Explorer and select **View in Browser**.
13. In the Web Site URL Required dialog, enter `http://localhost/user1` for the URL and click **OK**.

> **NOTE**
>
> If you get a error indicating an inability to load the type /_Default, make sure that you are running ASP.NET 2.0 on your Web site and not an earlier version. You can do that from the ASP.NET tab in Internet Information Services.

Opening Web Projects

Opening Web projects is similar to creating projects. The following sections call out areas to keep an eye out for while working within the IDE. It also covers working with Web projects using HTTP and FTP.

To open a Web project, select Open Web Site from the File menu. You will be prompted with the same Choose Location dialog covered previously and you have the same four options available to you: File System, Local IIS, FTP, and Remote Site.

File System

As indicated previously in this module, Visual Studio no longer uses a project file. Therefore, if you choose to open a Web site from the file system, you actually have the option of choosing any folder that you wish, even if the folder you choose was not created as a Web project initially in Visual Studio. For example, you can choose to open the My Documents folder as a Web site and Visual Studio will happily open it and display your files as shown below.

Figure 6: *My Documents* Opened As a Web Site

Because Visual Studio only creates additional files and folders when necessary, no additional files or folders are added to the location you open. A side-effect of this architecture is that it prevents you from nesting Web sites on the file system. For example, consider the following directory structure.

Web project at C:/MyWebSite

Another web project at C:/MyWebSite/Nested

When you open the Web site at c:/MyWebSite, the Nested folder will appear as a sub-folder of that application.

HTTP

When opening Web sites via HTTP, settings are read either from the IIS metabase (Local IIS) or using FrontPage Server Extensions (Remote Site.) If there are nested web applications, these are displayed as well with an icon identifying them as an application. If you are familiar with working with web applications in FrontPage, the behavior in Visual Studio 2005 is similar.

Even though Visual Studio will display an icon for applications that are nested beneath the application that is currently opened within the IDE, it will not allow you to expand them to see their content. You can, however, double-click on them to open them. When you do, you will be presented with a dialog prompting you to either open the web application (and replace the currently open solution) or add the Web application to your current solution.

Figure 7: Double-clicking a nested application icon presents you with this dialog

FTP Site

When you open a site via FTP, the files are all copied locally to your temp folder. The full path for the local storage location is displayed in the Properties pane for the project and is created using the following format.

C:/Documents and Settings/<User>/Local Settings/Temp/VWDWebCache/<Server>/_<application name>

When using FTP, Visual Studio will need to specify the base URL for your project so that you can browse it as shown below. If you do not specify a base URL, Visual Studio will ask you for it the first time you attempt to browse a page in the Web site.

Figure 8: Specifying a Base URL for FTP Sites

Improvements in Compilation

Working with Web applications in Visual Studio 2005 is noticeably faster than previous versions. This is due in no small part to the changes in compilation architecture.

In Visual Studio 2002 and 2003, Web applications were compiled into one primary assembly residing in the /bin folder. In Visual Studio 2005, an App/_Code folder was added. Classes and other non-UI code are added to the App/_Code folder. When Visual Studio builds the project, all files in the App/_Code folder are compiled into a single App/_Code.dll file. The result of this change is that subsequent builds are much faster than in previous versions.

> **NOTE**
>
> The MSBuild command line utility can also be used to build ASP.NET Web applications. That tool will be covered in module 9.

Another compilation enhancement is the new Build Page option on the Build menu. This feature allows a developer to rebuild only the current page (along with, of course, and dependencies) so that changes can be compiled more

quickly. Because C# does not offer background compilation for purposes of updating IntelliSense, etc., they will benefit immensely from this feature because it will allow for IntelliSense to be updated quickly by simply rebuilding a single page.

The Build properties for a project allow you to configure the type of build that occurs before the startup page is executed. Developers can choose to only build the current page so that Visual Studio can start debugging applications more quickly after code changes.

Figure 9: The Build Page Start Action

Another great enhancement to Visual Studio and the ASP.NET architecture is in the area of edit and continue. In Visual Studio 2005, developers can start debugging a project and make code changes on the project without detaching the debugger. In fact, you can literally start debugging a project, add a new class, add code to that class, add code to your page that creates a new instance of that class and execute a method of the class, all without detaching the debugger. Executing the new code is literally as easy as refreshing the browser!

Click here to see a video walkthrough of the edit and continue feature in Visual Studio 2005.

Open Full-Screen Video

The robust edit and continue functionality in ASP.NET 2.0 and Visual Studio 2005 is due to an architectural change for ASP.NET applications. In ASP.NET 1.x, applications created in Visual Studio 2002/2003 were compiled into a primary assembly that was stored in the /bin folder. All classes, pages, etc. for the application were compiled into that one DLL. Then at runtime, ASP.NET would compile all of the controls, markup, and ASP.NET code within pages and copy those DLLs into the ASP.NET temporary folder.

In Visual Studio 2005 using ASP.NET 2.0, the two compilation models outline above (one for Visual Studio and one for ASP.NET at runtime) have been merged into one common compilation model. That means that all compilation issues are now caught during the development stage instead of at runtime. It also allows for designer and IntelliSense support for features such as user controls and master pages.

Click here to see a video walkthrough of designer support for user controls.

Open Full-Screen Video

> **NOTE**
>
> When a user control is removed from a page, the @Register directive remains in the markup and should be removed manually in order to avoid parser errors if the user control is deleted from the Web site.

Another improvement in the Visual Studio compilation model is the Publish Web Site feature. Because the Publish feature precompiles the Web site, developers can enjoy the added performance of not having to compile anything on demand. It also precompiles all source code in the App/_Code folder into a DLL so that no source code has to be deployed.

Figure 10: The Publish Web Site Dialog

> **NOTE**
>
> The aspnet/_compile.exe utility can also be used to pre-compile an ASP.NET Web application. That tool will be covered in module 9.

When you Publish a Web site, the precompiled files are stored in the Temporary ASP.NET Files folder as shown below. Files with a *.compiled* file extension are XML files that define dependencies for particular DLLs. Any Webform or user controls are compiled into random DLLs that begin with *App/Web/*.

If you leave the *Allow this precompiled site to be updatable* checkbox checked, markup inside of your Webforms and user controls will not be pre-compiled into a DLL allowing you to make changes after deployment. If you would prefer to lock down the markup so that changes to the deployed content are not allowed, uncheck this box.

The *Use fixed naming and single page assemblies* checkbox allows you to disable batch compilation so that each

page is compiled into a fixed-named assembly. Leaving this box unchecked allows you to take advantage of batch compilation.

The *Enable strong naming on precompiled assemblies* checkbox allows you to strong-name your precompiled assemblies.

> **NOTE**
>
> In ASP.NET 1.x, strong-named assemblies had to be installed into the Global Assembly Cache (GAC). In ASP.NET 2.0, you are not required to install strong-named assemblies into the GAC.

Figure 11: An ASP.NET Applications Pre-Compiled Files

> **NOTE**
>
> In the application above, there was no web.config file. If there had been, it would have been called *PrecompiledApp.config* after the Publish Web site process.

Improvements in Deployment

As with Visual Studio 2002 and 2003, Visual Studio 2005 offers a Copy Project feature. However, the feature has been beefed up in Visual Studio 2005 and is now called Copy Web Site.

The Copy Web Site dialog is split into a left frame and a right frame. The left frame is called the Source Web Site and the right frame is called the Remote Web Site. One thing that may confuse some developers is that the site displayed in the right frame is not necessarily a remote site. It could be a site on the local file system or on the local instance of IIS. Additionally, the site displayed in the left frame is not necessarily the source Web site because the dialog allows you to publish from the remote Web site *to* the source Web site.

If you are copying a project to a remote Web site, that site must have the FrontPage Server Extensions installed on it. If it does not, you will need to connect using FTP. On the other hand, if you are copying a project to the local IIS instance, FrontPage Server Extensions are not required.

> **NOTE**
> If you try to create a new Web site on the local IIS instance and the FrontPage 2002 Server Extensions are installed, you will get an error message telling you that creating Web sites is not supported on a SharePoint server. In that case, you have the option of installing the FrontPage 2000 Server Extensions or removing the FrontPage Server Extensions.

Click here for a video walkthrough of the Copy Web Site feature.

Open Full-Screen Video

Improvements in Debugging

There are four key improvements in debugging in Visual Studio 2005.

- Debugging locally as a non-administrator is possible out of the box.
- The Debug attribute for the Compilation element is now false by default.
- Remote debugging setup and configuration is easier than before.
- You can now debug a Web site opened via an FTP location.

Debugging as a Non-Administrator

The addition of the ASP.NET Development Server allows non-administrators to easily debug ASP.NET applications right out of the box. When an ASP.NET application running on the local file system is debugged, Visual Studio launches the ASP.NET Development Server under the context of the logged-on user. That user can then debug that application without any additional configuration.

Debug is False by Default

In ASP.NET 1.x, the *debug* attribute in the *compilation* element of the web.config file was set to *true* by default. It has always been recommended that developers set this attribute to *false* before deploying an application to production, but because most developers don't fully understand the consequences of leaving the debug attribute set to true, they simply left it as-is.

The most severe problem with having the debug attribute set to true is that it disables ASP.NETs batch compilation model. Therefore, each page is compiled into a separate DLL. If a Web application consists of thousands of pages (not unheard of by any means), that means several thousand small DLLs will be created by that application. While these DLLs are small in size, they are not loaded into any particular location in memory. Therefore, they cause fragmentation in system memory and can contribute to OutOfMemoryException occurrences.

In ASP.NET 2.0, the debug attribute is set to false by default. As you have already seen, when a developer debugs an ASP.NET application in Visual Studio 2005, they are prompted to add a web.config file with debugging enabled. Doing so incurs the same drawbacks that were present in ASP.NET 1.x, but now the developer is clearly warned that the attribute should be reset to false before moving the application to production.

Remote Debugging Setup and Configuration

In Visual Studio 2002/2003, remote debugging relied on the Machine Debug Manager (mdm.exe) and the vs7jit.exe process. Because of that, troubleshooting remote debugging problems was often a black box for customers and it was often not much better for PSS.

Visual Studio 2005 removes the reliance on the mdm.exe and vs7jit.exe processes. Instead, it now uses the Remote Debug Monitor service (msvsmon.exe.)

The requirement for debugging in Visual Studio 2005 remotely is quite simple. You need to run msvsmon.exe on the remote server prior to debugging. You can install the Remote Debug Monitor from the Visual Studio CD or you can simply run msvsmon.exe from a share without installing anything at all on the Web server.

When you run msvsmon.exe, it is likely that it will complain about ports being blocked for remote debugging. Fortunately, you can easily unblock the ports from right within the warning dialog as shown below.

Figure 12: Notification that Windows Firewall is Blocking Remote Debugging

Once you have unblocked the ports necessary for debugging, you will see the Remote Debugging Monitor as shown below. From this interface, you can monitor connections and change debugging permissions easily.

Figure 13: The Remote Debugging Monitor

It is also possible to remotely debug a Web application opened via FTP. The steps are the same as those previously covered. However, you will need to specify a base URL for browsing the FTP project as outlined earlier in this module.

Lab 2

Remote Debugging with Visual Studio 2005

This lab will walk you through remote debugging with Visual Studio 2005.

Click here for a video walkthrough of this lab.

Open Full-Screen Video

This lab requires you to have two machines, one running Visual Studio 2005 and the other running IIS 5 or greater.

1. Open Visual Studio 2005 and create a new Web site on the remote server.

> **NOTE**
>
> You can create the Web site on a remote IIS instance or via FTP.

1. From the remote Web server, locate msvsmon.exe on the development machine using a UNC path and execute it.
   The default location for msvsmon.exe is //server/c$/Program Files/Microsoft Visual Studio 8/Common7/IDE/Remote Debugger/x86.
2. If prompted to unblock ports for remote debugging, do so.
3. From the development machine, open the code-behind for Default.aspx and set a breakpoint in the Page/_Load method.
4. Start debugging from the development machine.

You should hit the breakpoint as expected.

ASP.NET Development Server

As we've already discussed, Visual Studio 2005 ships with a Web server called the ASP.NET Development Server. (The ASP.NET Development Server is sometimes referred to as Cassini.) This Web server is a convenient means to browse and debug Web applications running on the file system.

The ASP.NET Development Server is a restricted Web server. It does not allow remote connections, it does not allow any requests from any user other than the user who started the Web server. It also does not have the capability of serving ASP pages. Only ASP.NET resources and HTML resources (including images, CSS files, etc.) are served.

The ASP.NET Development Server can be launched via the command line by running the WebDev.WebServer.exe file located at c:/Windows/Microsoft.NET/Framework/v2.0.////*. The following dialog displays the parameters that are available.

Figure 14

NOTE

The ASP.NET Development Server is not supported when launched explicitly via the command line.

The ASP.NET 2.0 Page Model

4/10/2020 • 26 minutes to read • Edit Online

by Microsoft

> In ASP.NET 1.x, developers had a choice between an inline code model and a code-behind code model. Code-behind could be implemented using either the Src attribute or the CodeBehind attribute of the @Page directive. In ASP.NET 2.0, developers still have a choice between inline code and code-behind, but there have been significant enhancements to the code-behind model.

In ASP.NET 1.x, developers had a choice between an inline code model and a code-behind code model. Code-behind could be implemented using either the Src attribute or the CodeBehind attribute of the @Page directive. In ASP.NET 2.0, developers still have a choice between inline code and code-behind, but there have been significant enhancements to the code-behind model.

Improvements in the Code-Behind Model

In order to fully understand the changes in the code-behind model in ASP.NET 2.0, its best to quickly review the model as it existed in ASP.NET 1.x.

The Code-Behind Model in ASP.NET 1.x

In ASP.NET 1.x, the code-behind model consisted of an ASPX file (the Webform) and a code-behind file containing programming code. The two files were connected using the @Page directive in the ASPX file. Each control on the ASPX page had a corresponding declaration in the code-behind file as an instance variable. The code-behind file also contained code for event binding and generated code necessary for the Visual Studio designer. This model worked fairly well, but because every ASP.NET element in the ASPX page required corresponding code in the code-behind file, there was no true separation of code and content. For example, if a designer added a new server control to an ASPX file outside of the Visual Studio IDE, the application would break due to the absence of a declaration for that control in the code-behind file.

The Code-Behind Model in ASP.NET 2.0

ASP.NET 2.0 greatly improves upon this model. In ASP.NET 2.0, code-behind is implemented using the new *partial classes* provided in ASP.NET 2.0. The code-behind class in ASP.NET 2.0 is defined as a partial class meaning that it contains only part of the class definition. The remaining part of the class definition is dynamically generated by ASP.NET 2.0 using the ASPX page at runtime or when the Web site is precompiled. The link between the code-behind file and the ASPX page is still established using the @ Page directive. However, instead of a CodeBehind or Src attribute, ASP.NET 2.0 now uses the CodeFile attribute. The Inherits attribute is also used to specify the class name for the page.

A typical @ Page directive might look like this:

```
<%@Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs" Inherits="_Default" %>
```

A typical class definition in an ASP.NET 2.0 code-behind file might look like this:

```
public partial class _Default : System.Web.UI.Page
```

> **NOTE**
> C# and Visual Basic are the only managed languages that currently support partial classes. Therefore, developers using J# will not be able to use the code-behind model in ASP.NET 2.0.

The new model enhances the code-behind model because developers will now have code files that contain only the code that they have created. It also provides for a true separation of code and content because there are no instance variable declarations in the code-behind file.

> **NOTE**
> Because the partial class for the ASPX page is where event binding takes place, Visual Basic developers can realize a slight performance increase by using the Handles keyword in code-behind to bind events. C# has no equivalent keyword.

New @ Page Directive Attributes

ASP.NET 2.0 adds many new attributes to the @ Page directive. The following attributes are new in ASP.NET 2.0.

Async

The Async attribute allows you to configure page to be executed asynchronously. Well cover asynchronous pages later in this module.

AsyncTimeout

Specified the timeout for asynchronous pages. The default is 45 seconds.

CodeFile

The CodeFile attribute is the replacement for the CodeBehind attribute in Visual Studio 2002/2003.

CodeFileBaseClass

The CodeFileBaseClass attribute is used in cases where you want multiple pages to derive from a single base class. Because of the implementation of partial classes in ASP.NET, without this attribute, a base class that uses shared common fields to reference controls declared in an ASPX page would not work properly because ASP.NETs compilation engine will automatically create new members based on controls in the page. Therefore, if you want a common base class for two or more pages in ASP.NET, you will need to define specify your base class in the CodeFileBaseClass attribute and then derive each pages class from that base class. The CodeFile attribute is also required when this attribute is used.

CompilationMode

This attribute allows you to set the CompilationMode property of the ASPX page. The CompilationMode property is an enumeration containing the values **Always**, **Auto**, and **Never**. The default is **Always**. The **Auto** setting will prevent ASP.NET from dynamically compiling the page if possible. Excluding pages from dynamic compilation increases performance. However, if a page that is excluded contains that code that must be compiled, an error will be thrown when the page is browsed.

EnableEventValidation

This attribute specifies whether or not postback and callback events are validated. When this is enabled, arguments to postback or callback events are checked to ensure that they originated from the server control that originally

rendered them.

EnableTheming

This attribute specifies whether or not ASP.NET themes are used on a page. The default is **false**. ASP.NET themes are covered in Module 10.

LinePragmas

This attribute specifies whether line pragmas should be added during compilation. Line pragmas are options used by debuggers to mark specific sections of code.

MaintainScrollPositionOnPostback

This attribute specifies whether or not JavaScript is injected into the page in order to maintain scroll position between postbacks. This attribute is **false** by default.

When this attribute is **true**, ASP.NET will add a <script> block on postback that looks like this:

```
<script src="/website/WebResource.axd?d=jBAvpwrdOM_V_Xzeox989A2 &t=632653133849531250" type="text/javascript">
</script>
```

Note that the src for this script block is WebResource.axd. This resource is not a physical path. When this script is requested, ASP.NET dynamically builds the script.

MasterPageFile

This attribute specifies the master page file for the current page. The path can be relative or absolute. Master pages are covered in Module 4.

StyleSheetTheme

This attribute allows you to override user-interface appearance properties defined by an ASP.NET 2.0 theme. Themes are covered in Module 10.

Theme

Specifies the theme for the page. If a value is not specified for the StyleSheetTheme attribute, the Theme attribute overrides all styles applied to controls on the page.

Title

Sets the title for the page. The value specified here will appear in the <title> element of the rendered page.

ViewStateEncryptionMode

Sets the value for the ViewStateEncryptionMode enumeration. The available values are **Always**, **Auto**, and **Never**. The default value is **Auto**. When this attribute is set to a value of **Auto**, viewstate is encrypted is a control requests it by calling the **RegisterRequiresViewStateEncryption** method.

Setting Public Property Values via the @ Page Directive

Another new capability of the @ Page directive in ASP.NET 2.0 is the ability to set the initial value of public properties of a base class. Suppose, for example, that you have a public property called **SomeText** in your base class and you d like it to be initialized to **Hello** when a page is loaded. You can accomplish this by simply setting the value in the @ Page directive like so:

```
<%@Page Language="C#" SomeText="Hello!" Inherits="PageBase" %>
```

The **SomeText** attribute of the @ Page directive sets the initial value of the SomeText property in the base class to *Hello!*. The video below is a walkthrough of setting the initial value of a public property in a base class using the @ Page directive.

Open Full-Screen Video

New Public Properties of the Page Class

The following public properties are new in ASP.NET 2.0.

AppRelativeTemplateSourceDirectory

Returns the application-relative path to the page or control. For example, for a page located at http://app/folder/page.aspx, the property returns ~/folder/.

AppRelativeVirtualPath

Returns the relative virtual directory path to the page or control. For example for a page located at http://app/folder/page.aspx, the property returns ~/folder/page.aspx.

AsyncTimeout

Gets or sets the timeout used for asynchronous page handling. (Asynchronous pages will be covered later in this module.)

ClientQueryString

A read-only property that returns the query string portion of the requested URL. This value is URL encoded. You can use the UrlDecode method of the HttpServerUtility class to decode it.

ClientScript

This property returns a ClientScriptManager object that can be used to manage ASP.NETs emission of client-side script. (The ClientScriptManager class is covered later in this module.)

EnableEventValidation

This property controls whether or not event validation is enabled for postback and callback events. When enabled, arguments to postback or callback events are verified to ensure that they originated from the server control that originally rendered them.

EnableTheming

This property gets or sets a Boolean that specifies whether or not an ASP.NET 2.0 theme applies to the page.

Form

This property returns the HTML form on the ASPX page as an HtmlForm object.

This property returns a reference to an HtmlHead object that contains the page header. You can use the returned HtmlHead object to get/set style sheets, Meta tags, etc.

IdSeparator

This read-only property gets the character that is used to separate control identifiers when ASP.NET is building a unique ID for controls on a page. It is not intended to be used directly from your code.

IsAsync

This property allows for asynchronous pages. Asynchronous pages are discussed later in this module.

IsCallback

This read-only property returns **true** if the page is the result of a call back. Call backs are discussed later in this module.

IsCrossPagePostBack

This read-only property returns **true** if the page is part of a cross-page postback. Cross-page postbacks are covered later in this module.

Items

Returns a reference to an IDictionary instance that contains all objects stored in the pages context. You can add items to this IDictionary object and they will be available to you throughout the lifetime of the context.

MaintainScrollPositionOnPostBack

This property controls whether or not ASP.NET emits JavaScript that maintains the pages scroll position in the browser after a postback occurs. (Details of this property were discussed earlier in this module.)

Master

This read-only property returns a reference to the MasterPage instance for a page to which a master page has been applied.

MasterPageFile

Gets or sets the master page filename for the page. This property can only be set in the PreInit method.

MaxPageStateFieldLength

This property gets or sets the maximum length for the pages state in bytes. If the property is set to a positive number, the pages view state will be broken up into multiple hidden fields so that it doesnt exceed the number of bytes specified. If the property is a negative number, the view state will not be broken into chunks.

PageAdapter

Returns a reference to the PageAdapter object that modifies the page for the requesting browser.

PreviousPage

Returns a reference to the previous page in cases of a Server.Transfer or a cross-page postback.

SkinID

Specifies the ASP.NET 2.0 skin to apply to the page.

StyleSheetTheme

This property gets or sets the style sheet that is applied to a page.

TemplateControl

Returns a reference to the containing control for the page.

Theme

Gets or sets the name of the ASP.NET 2.0 theme applied to the page. This value must be set prior to the PreInit method.

Title

This property gets or sets the title for the page as obtained from the pages header.

ViewStateEncryptionMode

Gets or sets the ViewStateEncryptionMode of the page. See a detailed discussion of this property earlier in this module.

New Protected Properties of the Page Class

The following are the new protected properties of the Page class in ASP.NET 2.0.

Adapter

Returns a reference to the ControlAdapter that renders the page on the device that requested it.

AsyncMode

This property indicates whether or not the page is processed asynchronously. It is intended for use by the runtime and not directly in code.

ClientIDSeparator

This property returns the character used as a separator when creating unique client IDs for controls. It is intended for use by the runtime and not directly in code.

PageStatePersister

This property returns the PageStatePersister object for the page. This property is primarily used by ASP.NET control developers.

UniqueFilePathSuffix

This property returns a unique suffix that is appended to the file path for caching browsers. The default value is __ufps= and a 6-digit number.

New Public Methods for the Page Class

The following public methods are new to the Page class in ASP.NET 2.0.

AddOnPreRenderCompleteAsync

This method registers event handler delegates for asynchronous page execution. Asynchronous pages are discussed later in this module.

ApplyStyleSheetSkin

Applies the properties in a pages style sheet to the page.

ExecuteRegisteredAsyncTasks

This method beings an asynchronous task.

GetValidators

Returns a collection of validators for the specified validation group or the default validation group if none is specified.

RegisterAsyncTask

This method registers a new async task. Asynchronous pages are covered later in this module.

RegisterRequiresControlState

This method tells ASP.NET that the pages control state must be persisted.

RegisterRequiresViewStateEncryption

This method tells ASP.NET that the pages viewstate requires encryption.

ResolveClientUrl

Returns a relative URL that can be used for client requests for images, etc.

SetFocus

This method will set the focus to the control that is specified when the page is initially loaded.

UnregisterRequiresControlState

This method will unregister the control that is passed to it as no longer requiring control state persistence.

Changes to the Page Lifecycle

The page lifecycle in ASP.NET 2.0 hasn't changed dramatically, but there are some new methods that you should be aware of. The ASP.NET 2.0 page lifecycle is outlined below.

PreInit (New in ASP.NET 2.0)

The PreInit event is the earliest stage in the lifecycle that a developer can access. The addition of this event makes it possible to programmatically change ASP.NET 2.0 themes, master pages, access properties for an ASP.NET 2.0 profile, etc. If you are in a postback state, its important to realize that Viewstate has not yet been applied to controls at this point in the lifecycle. Therefore, if a developer changes a property of a control at this stage, it will likely be overwritten later in the pages lifecycle.

Init

The Init event has not changed from ASP.NET 1.x. This is where you would want to read or initialize properties of controls on your page. At this stage, master pages, themes, etc. are already applied to the page.

InitComplete (New in 2.0)

The InitComplete event is called at the end of the pages initialization stage. At this point in the lifecycle, you can access controls on the page, but their state has not yet been populated.

PreLoad (New in 2.0)

This event is called after all postback data has been applied and just prior to Page_Load.

Load

The Load event has not changed from ASP.NET 1.x.

LoadComplete (New in 2.0)

The LoadComplete event is the last event in the pages load stage. At this stage, all postback and viewstate data has been applied to the page.

PreRender

If you would like for viewstate to be properly maintained for controls that are added to the page dynamically, the PreRender event is the last opportunity to add them.

PreRenderComplete (New in 2.0)

At the PreRenderComplete stage, all controls have been added to the page and the page is ready to be rendered. The PreRenderComplete event is the last event raised before the pages viewstate is saved.

SaveStateComplete (New in 2.0)

The SaveStateComplete event is called immediately after all page viewstate and control state has been saved. This is the last event before the page is actually rendered to the browser.

Render

The Render method has not changed since ASP.NET 1.x. This is where the HtmlTextWriter is initialized and the page is rendered to the browser.

Cross-Page Postback in ASP.NET 2.0

In ASP.NET 1.x, postbacks were required to post to the same page. Cross-page postbacks were not allowed. ASP.NET 2.0 adds the ability to post back to a different page via the IButtonControl interface. Any control that implements the new IButtonControl interface (Button, LinkButton, and ImageButton in addition to third-party custom controls) can take advantage of this new functionality via the use of the PostBackUrl attribute. The following code shows a Button control that posts back to a second page.

```
<asp:Button ID="SubmitReport" PostBackUrl="~/Default.aspx" runat="server" Text="Submit Report" />
```

When the page is posted back, the Page that initiates the postback is accessible via the PreviousPage property on the second page. This functionality is implemented via the new WebForm_DoPostBackWithOptions client-side function that ASP.NET 2.0 renders to the page when a control posts back to a different page. This JavaScript function is provided by the new WebResource.axd handler which emits script to the client.

The video below is a walkthrough of a cross-page postback.

Open Full-Screen Video

More Details on Cross-Page Postbacks

Viewstate

You may have asked yourself already about what happens to the viewstate from the first page in a cross-page postback scenario. After all, any control that does not implement IPostBackDataHandler will persist its state via viewstate, so to have access to the properties of that control on the second page of a cross-page postback, you must have access to the viewstate for the page. ASP.NET 2.0 takes care of this scenario using a new hidden field in the second page called __PREVIOUSPAGE. The __PREVIOUSPAGE form field contains the viewstate for the first page so that you can have access to the properties of all controls in the second page.

Circumventing FindControl

In the video walkthrough of a cross-page postback, I used the FindControl method to get a reference to the TextBox control on the first page. That method works well for that purpose, but FindControl is expensive and it requires writing additional code. Fortunately, ASP.NET 2.0 provides an alternative to FindControl for this purpose that will work in many scenarios. The PreviousPageType directive allows you to have a strongly-typed reference to the previous page by using either the TypeName or the VirtualPath attribute. The TypeName attribute allows you to specify the type of the previous page while the VirtualPath attribute allows you to refer to the previous page using a virtual path. After you've set the PreviousPageType directive, you must then expose the controls, etc. to which you want to allow access using public properties.

Lab 1 Cross-Page Postback

In this lab, you will create an application that uses the new cross-page postback functionality of ASP.NET 2.0.

1. Open Visual Studio 2005 and create a new ASP.NET Web site.

2. Add a new Webform called page2.aspx.
3. Open the Default.aspx in Design view and add a Button control and a TextBox control.
   a. Give the Button control an ID of **SubmitButton** and the TextBox control an ID of **UserName**.
   b. Set the PostBackUrl property of the Button to page2.aspx.
4. Open page2.aspx in Source view.
5. Add a @ PreviousPageType directive as shown below:
6. Add the following code to the Page_Load of page2.aspx's code-behind:

```
Response.Write(PreviousPage.UserName.Text);
```

7. Build the project by clicking on Build on the Build menu.
8. Add the following code to the code-behind for Default.aspx:

```
public TextBox txtUserName {
    get { return this.UserName; }
}
```

9. Change the Page_Load in page2.aspx to the following:

```
Response.Write(PreviousPage.txtUserName.Text);
```

10. Build the project.
11. Run the project.
12. Enter your name in the TextBox and click the button.
13. What is the result?

Asynchronous Pages in ASP.NET 2.0

Many contention problems in ASP.NET are caused by latency of external calls (such as Web service or database calls), file IO latency, etc. When a request is made against an ASP.NET application, ASP.NET uses one of its worker threads to service that request. That request owns that thread until the request is complete and the response has been sent. ASP.NET 2.0 seeks to resolve latency issues with these types of issues by adding the capability to execute pages asynchronously. That means that a worker thread can start the request and then hand off additional execution to another thread, thereby returning to the available thread pool quickly. When the file IO, database call, etc. has completed, a new thread is obtained from the thread pool to finish the request.

The first step in making a page execute asynchronously is to set the **Async** attribute of the page directive like so:

```
<%@ Page Async="true" %>
```

This attribute tells ASP.NET to implement the IHttpAsyncHandler for the page.

The next step is to call the AddOnPreRenderCompleteAsync method at a point in the lifecycle of the page prior to PreRender. (This method is typically called in Page_Load.) The AddOnPreRenderCompleteAsync method takes two parameters; a BeginEventHandler and an EndEventHandler. The BeginEventHandler returns an IAsyncResult which is then passed as a parameter to the EndEventHandler.

The video below is a walkthrough of an asynchronous page request.

Open Full-Screen Video

> **NOTE**
>
> An async page does not render to the browser until the EndEventHandler has completed. No doubt but that some developers will think of async requests as being similar to async callbacks. It's important to realize that they are not. The benefit to asynchronous requests is that the first worker thread can be returned to the thread pool to service new requests, thereby reducing contention due to being IO bound, etc.

Script Callbacks in ASP.NET 2.0

Web developers have always looked for ways to prevent the flickering associated with a callback. In ASP.NET 1.x, SmartNavigation was the most common method for avoiding flickering, but SmartNavigation caused problems for some developers because of the complexity of its implementation on the client. ASP.NET 2.0 addresses this issue with script callbacks. Script callbacks utilize XMLHttp to make requests against the Web server via JavaScript. The XMLHttp request returns XML data that can then be manipulated via the browser's DOM. XMLHttp code is hidden from the user by the new WebResource.axd handler.

There are several steps that are necessary in order to configure a script callback in ASP.NET 2.0.

Step 1 : Implement the ICallbackEventHandler Interface

In order for ASP.NET to recognize your page as participating in a script callback, you must implement the ICallbackEventHandler interface. You can do this in your code-behind file like so:

```
public partial class _Default : System.Web.UI.Page, ICallbackEventHandler
```

You can also do this using the @ Implements directive like so:

```
<%@ Implements Interface="System.Web.UI.ICallbackEventHandler" %>
```

You would typically use the @ Implements directive when using inline ASP.NET code.

Step 2 : Call GetCallbackEventReference

As mentioned previously, the XMLHttp call is encapsulated in the WebResource.axd handler. When your page is rendered, ASP.NET will add a call to WebForm_DoCallback, a client script that is provided by WebResource.axd. The WebForm_DoCallback function replaces the __doPostBack function for a callback. Remember that __doPostBack programmatically submits the form on the page. In a callback scenario, you want to prevent a postback, so __doPostBack will not suffice.

> **NOTE**
> __doPostBack is still rendered to the page in a client script callback scenario. However, it's not used for the callback.

The arguments for the WebForm_DoCallback client-side function are provided via the server-side function GetCallbackEventReference which would normally be called in Page_Load. A typical call to GetCallbackEventReference might look like this:

```
// Set up the JavaScript callback string cbRef = cm.GetCallbackEventReference(this,
"document.getElementById('ddlCompany').value", "ShowCompanyName", "null", true);
```

> **NOTE**
> In this case, cm is an instance of ClientScriptManager. The ClientScriptManager class will be covered later in this module.

There are several overloaded versions of GetCallbackEventReference. In this case, the arguments are as follows:

`this`

A reference to the control where GetCallbackEventReference is being called. In this case, it's the page itself.

```
document.getElementById('ddlCompany').value
```

A string argument that will be passed from the client-side code to the server-side event. In this case, Im passing the value of a dropdown called ddlCompany.

`ShowCompanyName`

The name of the client-side function that will accept the return value (as string) from the server-side callback event. This function will only be called when the server-side callback is successful. Therefore, for the sake of robustness, it is generally recommended to use the overloaded version of GetCallbackEventReference that takes an additional string argument specifying the name of a client-side function to execute in the event of an error.

`null`

A string representing a client-side function that it initiated before the callback to the server. In this case, there is no such script, so the argument is null.

`true`

A Boolean specifying whether or not to conduct the callback asynchronously.

The call to WebForm_DoCallback on the client will pass these arguments. Therefore, when this page is rendered on the client, that code will look like so:

```
WebForm_DoCallback('__Page',document.getElementById('ddlCompany').value, ShowCompanyName,null,null,true)
```

Notice that the signature of the function on the client is a bit different. The client-side function passes 5 strings and a Boolean. The additional string (which is null in the above example) contains the client-side function that will handle any errors from the server-side callback.

Step 3 : Hook the Client-Side Control Event

Notice that the return value of GetCallbackEventReference above was assigned to a string variable. That string is

used to hook a client-side event for the control that initiates the callback. In this example, the callback is initiated by a dropdown on the page, so I want to hook the *OnChange* event.

To hook the client-side event, simply add a handler to the client-side markup as follows:

```
// Hook the JavaScript function to the onchange event of the dropdown ddlCompany.Attributes["onchange"] =
String.Format("javascript:{0}", cbRef);
```

Recall that *cbRef* is the return value from the call to GetCallbackEventReference. It contains the call to WebForm_DoCallback that was shown above.

Step 4 : Register the Client-Side Script

Recall that the call to GetCallbackEventReference specified that a client-side script called **ShowCompanyName** would be executed when the server-side callback succeeds. That script needs to be added to the page using a ClientScriptManager instance. (The ClientScriptManager class will be discussed later in this module.) You do that like so:

```
System.Text.StringBuilder clientScript = new System.Text.StringBuilder(""); ClientScriptManager cm =
Page.ClientScript; // Create the client script clientScript.Append("function ShowCompanyName(companyName)");
clientScript.Append("{"); clientScript.Append("document.getElementById('CoClicked').innerHTML = \"You chose \"
+ companyName + \".\";"); clientScript.Append("}"); cm.RegisterClientScriptBlock(this.GetType(), "showCo",
clientScript.ToString(), true);
```

Step 5 : Call the Methods of the ICallbackEventHandler Interface

The ICallbackEventHandler contains two methods that you need to implement in your code. They are **RaiseCallbackEvent** and **GetCallbackEvent**.

RaiseCallbackEvent takes a string as an argument and returns nothing. The string argument is passed from the client-side call to WebForm_DoCallback. In this case, that value is the *value* attribute of the dropdown called ddlCompany. Your server-side code should be placed in the RaiseCallbackEvent method. For example, if your callback is making a WebRequest against an external resource, that code should be placed in RaiseCallbackEvent.

GetCallbackEvent is responsible for processing the return of the callback to the client. It takes no arguments and returns a string. The string that it returns will be passed as an argument to the client-side function, in this case *ShowCompanyName*.

Once you have completed the above steps, you are ready to perform a script callback in ASP.NET 2.0.

Open Full-Screen Video

Script callbacks in ASP.NET are supported in any browser that supports making XMLHttp calls. That includes all of the modern browsers in use today. Internet Explorer uses the XMLHttp ActiveX object while other modern browsers (including the upcoming IE 7) use an intrinsic XMLHttp object. To programmatically determine if a

browser supports callbacks, you can use the **Request.Browser.SupportCallback** property. This property will return **true** if the requesting client supports script callbacks.

Working with Client Script in ASP.NET 2.0

Client scripts in ASP.NET 2.0 are managed via the use of the ClientScriptManager class. The ClientScriptManager class keeps track of client scripts using a type and a name. This prevents the same script from being programmatically inserted on a page more than once.

> **NOTE**
> After a script has been successfully registered on a page, any subsequent attempt to register the same script will simply result in the script not being registered a second time. No duplicate scripts are added and no exception occurs. To avoid unnecessary computation, there are methods that you can use to determine if a script is already registered so that you do not attempt to register it more than once.

The methods of the ClientScriptManager should be familiar to all current ASP.NET developers:

RegisterClientScriptBlock

This method adds a script to the top of the rendered page. This is useful for adding functions that will be explicitly called on the client.

There are two overloaded versions of this method. Three of four arguments are common among them. They are:

`type (string)`

The ***type*** argument identifies a type for the script. It is generally a good idea to use the page's type (this.GetType()) for the type.

`key (string)`

The ***key*** argument is a user-defined key for the script. This should be unique for each script. If you attempt to add a script with the same key and type of an already added script, it will not be added.

`script (string)`

The ***script*** argument is a string containing the actual script to add. It's recommended that you use a StringBuilder to create the script and then use the ToString() method on the StringBuilder to assign the ***script*** argument.

If you use the overloaded RegisterClientScriptBlock that only takes three arguments, you must include script elements (<script> and </script>) in your script.

You may choose to use the overload of RegisterClientScriptBlock that takes a fourth argument. The fourth argument is a Boolean that specifies whether or not ASP.NET should add script elements for you. If this argument is **true**, your script should not include the script elements explicitly.

Use the IsClientScriptBlockRegistered method to determine if a script has already been registered. This allows you to avoid an attempt to re-register a script that has already been registered.

RegisterClientScriptInclude (New in 2.0)

The RegisterClientScriptInclude tag creates a script block that links to an external script file. It has two overloads. One takes a key and a URL. The second adds a third argument specifying the type.

For example, the following code generates a script block that links to jsfunctions.js in the root of the scripts folder of the application:

```
ClientScriptManager cm = Page.ClientScript; if(!cm.IsClientScriptIncludeRegistered("jsfunc")) {
cm.RegisterClientScriptInclude(this.GetType(), "jsfunc", "/scripts/jsfunctions.js"); }
```

This code produces the following code in the rendered page:

```
<script src="/scripts/jsfunctions.js" type="text/javascript"></script>
```

> **NOTE**
> The script block is rendered at the bottom of the page.

Use the IsClientScriptIncludeRegistered method to determine if a script has already been registered. This allows you to avoid an attempt to re-register a script.

RegisterStartupScript

The RegisterStartupScript method takes the same arguments as the RegisterClientScriptBlock method. A script registered with RegisterStartupScript executes after the page loads but before the OnLoad client-side event. In 1.X, scripts registered with RegisterStartupScript were placed just before the closing </form> tag while scripts registered with RegisterClientScriptBlock were placed immediately after the opening <form> tag. In ASP.NET 2.0, both are placed immediately before the closing </form> tag.

> **NOTE**
> If you register a function with RegisterStartupScript, that function will not execute until you explicitly call it in client-side code.

Use the IsStartupScriptRegistered method to determine if a script has already been registered and avoid an attempt to re-register a script.

Other ClientScriptManager Methods

Here are some of the other useful methods of the ClientScriptManager class.

GETCALLBACKEVENTREFERENCE	SEE SCRIPT CALLBACKS EARLIER IN THIS MODULE.
GetPostBackClientHyperlink	Gets a JavaScript reference (javascript:<call>) that can be used to post back from a client-side event.
GetPostBackEventReference	Gets a string that can be used to initiate a post back from the client.
GetWebResourceUrl	Returns a URL to a resource that is embedded in an assembly. Must be used in conjunction with **RegisterClientScriptResource**.
RegisterClientScriptResource	Registers a Web resource with the page. These are resources embedded in an assembly and handled by the new WebResource.axd handler.
RegisterHiddenField	Registers a hidden form field with the page.

GETCALLBACKEVENTREFERENCE	SEE SCRIPT CALLBACKS EARLIER IN THIS MODULE.
RegisterOnSubmitStatement	Registers client-side code that executes when the HTML form is submitted.

Server Controls

> ASP.NET 2.0 enhances server controls in many ways. In this module, we'll cover some of the architectural changes to the way ASP.NET 2.0 and Visual Studio 2005 deals with server controls.

ASP.NET 2.0 enhances server controls in many ways. In this module, we'll cover some of the architectural changes to the way ASP.NET 2.0 and Visual Studio 2005 deals with server controls.

View state

The primary change in view state in ASP.NET 2.0 is a dramatic reduction in size. Consider a page with only a Calendar control on it. Here is the view state in ASP.NET 1.1.

```
dDwtMTg1NDkwMjc0Nzt0PDtsPGk8MT47PjtsPHQ8O2w8aTwxPjs
+O2w8dDxAMDxwPHA8bDxTRDs+O2w8bDxTeXN0ZW0uRGF0ZVRpbWUsIG1
zY29ybGliLCBWZXJzaW9uPTEuMC41MDAwLjAsIEN1bHR1cmU9bmV1dHJ
hbCwgUHVibGljS2V5VG9rZW49Yjc3YTVjNTYxOTM0ZTA4OTwyMDA1LTE
xLTA4Pjs+Oz4+Oz47Ozs7Ozs7Pjs7Pjs+Pjs+Pjs+lkX2YWqfACtP
/VWr8G03pob/+tU=
```

Now here's the view state on an identical page in ASP.NET 2.0.

```
/wEPDwULLTEzNjg5MjAxMzgPZBYCAgMPZBYCAgEPPCsAC
gEADxYCHgJTRBYBBgDAEX8OsscIZGRkllfArINjlhvzQX7Xfign2q6HK5E=
```

That's a pretty significant change, and considering that view state is carried back and forth over the wire, this change can give developers a significant performance increase. The reduction in size of view state is largely due to the way that we handle it internally. Remember that view state is a Base64 encoded string. To better understand the change in view state in ASP.NET 2.0, let's have a look at the decoded values from the examples above.

Here is the 1.1 view state decoded:

```
t<-1854902747;t<;l<i<1>;>;l<t<;l<
i<1>;>;l<t<@0<p<p<l<SD;>;l<l<
System.DateTime, mscorlib, Version=1.0.5000.0, Culture=neutral,
PublicKeyToken=b77a5c561934e089<2005-11-08>;>;>>;
>;;;;;;;;;;>;;>;>>;>>;>Eaj
```

This may look a bit like gibberish, but there is a pattern here. In ASP.NET 1.x, we used single characters to identify data-types and delimited values using the <> characters. The "t" in the view state sample above represents a Triplet. The Triplet contains a pair of ArrayLists (the "l" represents an ArrayList.) One of those ArrayLists contains an Int32 ("i") with a value of 1 and the other contains another Triplet. The Triplet contains a pair of ArrayLists, etc. The important thing to remember is that we use Triplets that contain pairs, we identify the data-types via a letter, and we use the < and > characters as delimiters.

In ASP.NET 2.0, the decoded view state looks a bit different.

```
-1368920138 d
 d

 SD
 dddWc A ('ك
```

You should notice a huge change in the appearance of the decoded view state. This change has several architectural underpinnings. View state in ASP.NET 1.x used the LosFormatter to serialize data. In 2.0, we use the new ObjectStateFormatter class. This class was specifically designed to aid in the serialization and deserialization of view state and control state. (Control state will be covered in the next section.) There are many benefits gained by changing the method by which serialization and deserialization take place. One of the most dramatic is the fact that unlike the LosFormatter which uses a TextWriter, the ObjectStateFormatter uses a BinaryWriter. This allows ASP.NET 2.0 to store view state a series of bytes instead of strings. Take, for example, an integer. In ASP.NET 1.1, an integer required 4 bytes of view state. In ASP.NET 2.0, that same integer only requires 1 byte. Other enhancements were made to decrease the amount of view state that is stored. DateTime values, for example, are now stored using a TickCount instead of a string.

As if all of that weren't enough, special attention was paid to the fact that one of the greatest consumers of view state in 1.x was the DataGrid and similar controls. A major drawback of controls such as the DataGrid where view state is concerned is that it often contains large amounts of repeated information. In ASP.NET 1.x, that repeated information was simply stored over and over again resulting in a bloated view state. In ASP.NET 2.0, we use the new IndexedString class to store such data. If a string repeats, we just store the token for the IndexedString and the index within a running table of IndexedString objects.

Control State

One of the major gripes that developers had with view state was the size that it added to the HTTP payload. As previously mentioned, one of the greatest consumers of view state is the DataGrid control. To avoid the huge amounts of view state generated by a DataGrid, many developers simply disabled view state for that control. Unfortunately, that solution wasn't always a good one. View state in ASP.NET 1.x contains not only data necessary for the correct functionality of the control. It also contains information concerning the state of the control's UI. This means that if you want to allow for pagination on a DataGrid, you must enable view state even if you don't need all of the UI information that view state contains. It's an all-or-nothing scenario.

In ASP.NET 2.0, control state solves that problem nicely via the introduction of control state. Control state contains the data that is absolutely necessary for the proper functionality of a control. Unlike view state, control state cannot be disabled. Therefore, it is important that the data being stored in control state is carefully controlled.

> **NOTE**
>
> Control state is persisted along with the view state in the __VIEWSTATE hidden form field.

This video is a walkthrough of view state and control state.

Open Full-Screen Video

In order for a server control to read and write to control state, you must take three steps.

Step 1: Call the RegisterRequiresControlState Method

The RegisterRequiresControlState method informs ASP.NET that a control needs to persist control state. It takes one argument of type Control which is the control that is being registered.

It is important to note that registration does not persist from request to request. Therefore, this method must be called on every request if a control is to persist control state. It is recommended that the method be called in OnInit.

```
protected override void OnInit(EventArgs e) { Page.RegisterRequiresControlState(this); base.OnInit(e); }
```

Step 2: Override SaveControlState

The SaveControlState method saves control state changes for a control since the last post back. It returns an object representing the control's state.

Step 3: Override LoadControlState

The LoadControlState method loads saved state into a control. The method takes one argument of type Object which holds the saved state for the control.

Full XHTML Compliance

Any Web developer knows the importance of standards in Web applications. In order to maintain a standards-based development environment, ASP.NET 2.0 is fully XHTML compliant. Therefore, all tags are rendered according to XHTML standards in browsers that support HTML 4.0 or greater.

The DOCTYPE definition in ASP.NET 1.1 was as follows:

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Transitional//EN
```

In ASP.NET 2.0, the default DOCTYPE definition is as follows:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
```

If you choose, you can alter the default XHTML compliance via the xhtmlConformance node in the configuration file. For example, the following node in the web.config file will change XHTML compliance to XHTML 1.0 Strict:

```
<xhtmlConformance mode="Strict" />
```

If you choose, you can also configure ASP.NET to use the legacy configuration used in ASP.NET 1.x as follows:

```
<xhtmlConformance mode="Legacy" />
```

Adaptive Rendering Using Adapters

In ASP.NET 1.x, the configuration file contained a <browserCaps> section that populated a HttpBrowserCapabilities object. This object allowed a developer to determine what device is making a particular request and render code appropriately. In ASP.NET 2.0, the model has improved and now uses the new ControlAdapter class. The ControlAdapter class overrides events in the control's lifecycle and controls the rendering of controls based upon the user agent's capabilities. The capabilities of a specific user agent are defined by a browser definition file (a file with a .browser file extension) stored in the c:\windows\microsoft.net\framework\v2.0.****\CONFIG\Browsers folder.

> **NOTE**
> The ControlAdapter class is an abstract class.

Much like the <browserCaps> section in 1.x, the browser definition file uses a Regular Expression to parse the user agent string in order to identify the requesting browser. It them defines particular capabilities for that user agent. The ControlAdapter renders the control via the Render method. Therefore, if you override the Render method, you should not call Render on the base class. Doing so may cause rendering to occur twice, once for the adapter and once for the control itself.

Developing a Custom Adapter

You can develop your own custom adapter by inheriting from ControlAdapter. Additionally, you can inherit from the abstract class PageAdapter in cases where an adapter is needed for a page. Mapping of controls to your custom adapter is accomplished via the <controlAdapters> element in the browser definition file. For example, the following XML from a browser definition file maps the Menu control to the MenuAdapter class:

```
<controlAdapters> <adapter controlType="System.Web.UI.WebControls.Menu"
adapterType="System.Web.UI.WebControls.Adapters.MenuAdapter" /> </controlAdapters>
```

Using this model, it becomes quite easy for a control developer to target a particular device or browser. It's also quite simple for a developer to have complete control over how pages render on every device.

Per-Device Rendering

Server control properties in ASP.NET 2.0 can be specified per-device using a browser-specific prefix. For example, the code below will change the Text of a label depending upon which device is being used to browse the page.

```
<asp:Label ID="lblBrowser" runat="server" Text="You are browsing from an unknown device." ie:Text="You are
browsing from Internet Explorer." mozilla:Text="You are browsing from Firefox."> </asp:Label>
```

When the page containing this label is browsed from Internet Explorer, the label will display text saying "You are browsing from Internet Explorer." When the page is browsed from Firefox, the label will display the text "You are browsing from Firefox." When the page is browsed from any other device, it will display "You are browsing from

an unknown device." Any property can be specified using this special syntax.

Setting Focus

ASP.NET 1.x developers frequently asked about how to set initial focus on a particular control. For example, on a login page, it's useful to have the User ID textbox get the focus when the page first loads. In ASP.NET 1.x, doing this required writing some client-side script. Even though such a script is a trivial task, it's no longer necessary in ASP.NET 2.0 thanks to the SetFocus method. The SetFocus method takes one argument indicating the control that should receive focus. This argument can either be the client ID of the control as a string or the name of the Server control as a Control object. For example, to set the initial focus to a TextBox control called txtUserID when the page first loads, add the following code to Page_Load:

```
if (!IsPostBack) {
    SetFocus(txtUserID);
}
```

-- or

```
if (!IsPostBack) {
    SetFocus(txtUserID.ClientID);
}
```

ASP.NET 2.0 uses the Webresource.axd handler (discussed previously) to render a client-side function that sets the focus. The name of the client-side function is WebForm_AutoFocus as shown here:

```
<script type="text/javascript"> <!-- WebForm_AutoFocus('txtUserID'); // --> </script>
```

Alternatively, you can use the Focus method for a control to set the initial focus to that control. The Focus method derives from the Control class and is available to all ASP.NET 2.0 controls. It is also possible to set focus to a particular control when a validation error occurs. That will be covered in a later module.

New Server Controls in ASP.NET 2.0

The following are new server controls in ASP.NET 2.0. We will go into more detail on some of them in later modules.

ImageMap Control

The ImageMap control allows you to add hotspots to an image that can initiate a post back or navigate to a URL. There are three types of hotspots available; CircleHotSpot, RectangleHotSpot, and PolygonHotSpot. Hotspots are added via a collection editor in Visual Studio or programmatically in code. There is no user-interface available for drawing hotspots on an image. The coordinates and size or radius of the hotspot must be specified declaratively. There is also no visual representation of a hotspot in the designer. If a hotspot is configured to navigate to a URL, the URL is specified via the NavigateUrl property of the hotspot. In the case of a post back hotspot, the PostBackValue property allows you to pass a string in the post back that can be retrieved in server-side code.

Figure 1: HotSpot Collection Editor in Visual Studio

BulletedList Control

The BulletedList control is a bulleted list that can easily be data bound. The list can be ordered (numbered) or unordered via the BulletStyle property. Each item in the list is represented by a ListItem object.

Figure 2: BulletedList Control in Visual Studio

HiddenField Control

The HiddenField control adds a hidden form field to your page, the value of which is available in server-side code. The value of a hidden form field is generally expected to remain unchanged between post backs. However, it is possible for a malicious user to change the value prior to post back. If this happens, the HiddenField control will raise the ValueChanged event. If you have sensitive information in the HiddenField control and you want to ensure that it remains unchanged, you should handle the ValueChanged event in your code.

FileUpload Control

The FileUpload control in ASP.NET 2.0 makes it possible to upload files to a Web server via an ASP.NET page. This control is quite similar to the ASP.NET 1.x HtmlInputFile class with a few exceptions. In ASP.NET 1.x, it was recommended that the PostedFile property be checked for null in order to determine if you had a good file. The FileUpload control in ASP.NET 2.0 adds a new HasFile property that you can use for the same purpose and it's a bit more efficient.

The PostedFile property is still available for access to an HttpPostedFile object, but some of the functionality of the HttpPostedFile is now available intrinsically with the FileUpload control. For example, to save an uploaded file in ASP.NET 1.x, you call the SaveAs method on the HttpPostedFile object. Using the FileUpload control in ASP.NET 2.0, you would call the SaveAs method on the FileUpload control itself.

Another significant change in the 2.0 behavior (and likely the most significant change) is that it is no longer necessary to load an entire uploaded file into memory before saving it. In 1.x, any file that was uploaded is saved entirely into memory prior to being written to disk. This architecture prevents the upload of large files.

In ASP.NET 2.0, the requestLengthDiskThreshold attribute of the httpRuntime element allows you to configure how many Kilobytes are held in a buffer in memory prior to being written to disk.

IMPORTANT: MSDN documentation (and documentation elsewhere) specifies that this value is in bytes (not Kilobytes) and that the default is 256. The value is actually specified in Kilobytes and the default value is 80. By having a default value of 80K, we ensure that the buffer does not end up on the large object heap.

Wizard Control

It is fairly common to encounter ASP.NET developers struggling with attempting to gather information in a series of "pages" using panels or by transferring from page to page. More often than not, the endeavor is a frustrating one and is time consuming. The new Wizard control solves the problems by allowing for linear and non-linear steps in a wizard interface that users are familiar with. The Wizard control presents input forms in a series of steps. Each step is of a particular type specified by the StepType property of the control. The available step types are as follows:

STEP TYPE	EXPLANATION
Auto	The wizard automatically determines the type of step based upon its position within the step hierarchy.
Start	The first step, often used to present an introductory statement.
Step	A normal step.
Finish	The final step, usually used to present a button to finish the wizard.
Complete	Presents a message communicating success or failure.

> **NOTE**
>
> The Wizard control keeps track of its state using ASP.NET control state. Therefore, the EnableViewState property can be set to false without any detriment.

This video is a walkthrough of the Wizard control.

Open Full-Screen Video

Localize Control

The Localize control is similar to a Literal control. However, the Localize control has a **Mode** property that controls how markup that is added to it is rendered. The Mode property supports the following values:

MODE	EXPLANATION
Transform	Markup is transformed according to the protocol of the browser making the request.
PassThrough	Markup is rendered as-is.
Encode	Markup that is added to the control is encoded using HtmlEncode.

MultiView and View Controls

The MultiView control acts as a container for View controls, and the View control acts as a container (much like a Panel control) for other controls. Each view in a MultiView control is represented by a single View control. The first View control in the MultiView is view 0, the second is view 1, etc. You can switch views by specifying the ActiveViewIndex of the MultiView control.

Substitution Control

The Substitution control is used in conjunction with ASP.NET caching. In cases where you want to take advantage of caching, but you have portions of a page that must be updated on each request (in other words, portions of a page that are exempt from caching), the Substitution component provides a great solution. The control doesn't actually render any output on its own. Instead, it is bound to a method in server-side code. When the page is requested, the method is called and the returned markup is rendered in place of the substitution control.

The method to which the Substitution control is bound is specified via the **MethodName** property. That method must meet the following criteria:

- It must be a static (shared in VB) method.
- It accepts one parameter of type HttpContext.
- It returns a string representing the markup that should replace the control on the page.

The Substitution control does not have the ability to modify any other control on the page, but it does have access to the current HttpContext via its parameter.

GridView Control

The GridView control is the replacement for the DataGrid control. This control will be covered in more detail in a later module.

DetailsView Control

The DetailsView control allows you to display a single record from a data source and to edit or delete it. It is covered in more detail in a later module.

FormView Control

The FormView control is used to display a single record from a datasource in a configurable interface. It is covered in more detail in a later module.

AccessDataSource Control

The AccessDataSource control is used to data bind an Access database. It is covered in more detail in a later module.

ObjectDataSource Control

The ObjectDataSource control is used to support a three-tier architecture so that controls can be data-bound to a middle-tier business object as opposed to a two-tiered model where controls are bound directly to the data source. It will be discussed in more detail in a later module.

XmlDataSource Control

The XmlDataSource control is used to data bind to an XML data source. It is covered in more detail in a later module.

SiteMapDataSource Control

The SiteMapDataSource control provides data binding for site navigation controls based on a site map. It will be discussed in more detail in a later module.

SiteMapPath Control

The SiteMapPath control displays a series of navigation links commonly referred to as breadcrumbs. It is covered in more detail in a later module.

Menu Control

The Menu control displays dynamic menus using DHTML. It is covered in more detail in a later module.

TreeView Control

The TreeView control is used to display a hierarchical tree view of data. It is covered in more detail in a later module.

Login Control

The Login control provides for a mechanism to log into a Web site. It is covered in more detail in a later module.

LoginView Control

The LoginView control allows for the display of different templates based upon a user's login status. It is covered in more detail in a later module.

PasswordRecovery Control

The PasswordRecovery control is used to retrieve forgotten passwords by users of an ASP.NET application. It is covered in more detail in a later module.

LoginStatus

The LoginStatus control displays a user's login status. It is covered in more detail in a later module.

LoginName

The LoginName control displays a user's username after being logged into an ASP.NET application. It is covered in more detail in a later module.

CreateUserWizard

The CreateUserWizard is a configurable wizard which gives users the ability to create an ASP.NET Membership account for use in an ASP.NET application. It is covered in more detail in a later module.

ChangePassword

The ChangePassword control allows users to change their password for an ASP.NET application. It is covered in more detail in a later module.

Various WebParts

ASP.NET 2.0 ships with various Web Parts. These will be covered in detail in a later module.

Master Pages

4/10/2020 • 10 minutes to read • Edit Online

by Microsoft

One of the key components to a successful Web site is a consistent look and feel. In ASP.NET 1.x, developers used user controls to replicate common page elements across a Web application. While that is certainly a workable solution, using user controls does have some drawbacks. For example, a change in position of a user control requires a change to multiple pages across a site. User controls are also not rendered in Design view after being inserted on a page.

One of the key components to a successful Web site is a consistent look and feel. In ASP.NET 1.x, developers used user controls to replicate common page elements across a Web application. While that is certainly a workable solution, using user controls does have some drawbacks. For example, a change in position of a user control requires a change to multiple pages across a site. User controls are also not rendered in Design view after being inserted on a page.

ASP.NET 2.0 introduces Master pages as a way of maintaining a consistent look and feel, and as you'll soon see, Master pages represent a significant improvement over the user control method.

Why Master Pages?

You may be wondering why master pages were needed in ASP.NET 2.0. After all, Web site developers are already using user controls in ASP.NET 1.x to share content areas between pages. There are actually several reasons why user controls are a less-than-optimal solution for creating a common layout.

User controls don't actually define page layout. Instead, they define the layout and functionality for a portion of a page. The distinction between these two is important because it makes manageability of a user control solution much more difficult. For example, when you want to change the position of a user control on your page, you must edit the actual page on which the user control appears. Thats fine if you have only a few pages, but in large sites, it quickly becomes a site management nightmare!

Another drawback of using user controls for defining a common layout is rooted in the architecture of ASP.NET itself. If any public member of a user control is changed, it requires you to recompile all of the pages that use the user control. In turn, ASP.NET will then re-JIT your pages when they are first accessed. This, once again, produces a non-scalable architecture and a site management problem for larger sites.

Both of these problems (and many more) are nicely addressed by master pages in ASP.NET 2.0.

How Master Pages Work

A master page is analogous to a template for other pages. Page elements that should be shared among other pages (i.e. menus, borders, etc.) are added to the master page. When new pages are added to the site, you can associate them with a master page. A page that is associated with a master page is called a **content page**. By default, a content page takes on the appearance from the master page. However, when you create a master page, you can define portions of the page that the content page can replace with its own content. These portions are defined using a new control introduced in ASP.NET 2.0; the **ContentPlaceHolder** control.

A master page can contain any number of ContentPlaceHolder controls (or none at all.) On the content page, the content from the ContentPlaceHolder controls appears inside of **Content** controls, another new control in ASP.NET 2.0. By default, the content pages Content controls are empty so that you can provide your own content. If you

want to use the content from the master page inside of the Content controls, you can do so as you will see later in this module. The Content control is mapped to the ContentPlaceHolder control via the ContentPlaceHolderID attribute of the Content control. The code below maps a Content control to a ContentPlaceHolder control called mainBody on a master page.

```
<asp:Content ID="Content1" ContentPlaceHolderID="mainBody" Runat="Server">
```

NOTE

You will often hear people describe master pages as being a base class for other pages. Thats actually not true. The relationship between master pages and content pages is not one of inheritance.

Figure 1 shows a master page and an associated content page as they appear in Visual Studio 2005. You can see the ContentPlaceHolder control in the master page and the corresponding Content control in the content page. Notice that the master pages content that is outside of the ContentPlaceHolder is visible but grayed out in the content page. Only the content inside of the ContentPlaceHolder can be supplanted by the content page. All other content that comes from the master page is immutable.

Figure 1: A master page and its associated content page

Creating a Master Page

To create a new master page:

1. Open Visual Studio 2005 and create a new Web site.
2. Click File, New, File.
3. Choose Master File from the Add New Item dialog as shown in **figure 2**.
4. Click Add.

Figure 2: Creating a New Master Page

Notice that the file extension for a master page is *.master*. This is one of the ways that a master page differs from an ordinary page. The other primary difference is that in lieu of a @Page directive, the master page contains a @Master directive. Switch to Source View for the master page you've just created and review the code.

A new master page will have one ContentPlaceHolder control by default. In most cases, it makes more sense to create the common page elements first and then insert ContentPlaceHolder controls where custom content is desired. In those cases, developers will want to delete the default ContentPlaceHolder control and insert new ones as the page is developed. ContentPlaceHolder controls are not resizable despite the fact that they do display sizing handles. The ContentPlaceHolder control sizes automatically based upon the content that it contains with one exception; if you place a ContentPlaceHolder control inside of a block element such as a table cell, it will size according to the size of the element.

Lab 1 Working with Master Pages

In this lab, you will create a new master page and define three ContentPlaceHolder controls. You will then create a new Content page and replace the content from at least one of the ContentPlaceHolder controls.

1. Create a master page and insert ContentPlaceHolder controls.

    a. Create a new master page as described above.
    b. Delete the default ContentPlaceHolder control.
    c. Select the ContentPlaceHolder control by clicking the shaded top border of the control and then delete it by hitting the DEL key on your keyboard.
    d. Insert a new table using the *Header and side* template as shown in figure 3. Change the width and height to 90% each so that the entire table is visible in the designer.

Figure 3

1. Place the cursor into each cell of the table and set the *valign* property to *top*.
2. From the Toolbox, insert a ContentPlaceHolder control in the top cell of the table (the header cell.)
3. When you insert this ContentPlaceHolder control, you will notice that the row height will take up almost the entire page as shown in figure 4. Don't be concerned about that at this point.

Figure 4: The empty space is in the same cell as the ContentPlaceHolder

1. Place a ContentPlaceHolder control in the other two cells. Once the other ContentPlaceHolder controls have been inserted, the size of the table cells should be as you would expect. The page should now look like the page shown in **figure 5**.

Figure 5: The Master with all ContentPlaceHolder controls. Notice that the cell height for the header cell is now what it should be

1. Enter some text of your choice into each of the three ContentPlaceHolder controls.
2. Save the master page as exercise1.master.
3. Create a new Web Form and associate it with the exercise1.master master page.
4. Select File, New, File in Visual Studio 2005.
5. Select **Web Form** in the Add New Item dialog.
6. Make sure that the Select master page checkbox is checked as shown in figure 6.

Figure 6: Adding a new Content Page

1. Click Add.
2. Select exercise1.master in the Select a master page dialog as shown in figure 7.
3. Click OK to add the new content page.

The new content page appears in Visual Studio with one Content control for each ContentPlaceHolder control on the master page. By default, the Content controls are empty so that you can add your own content. If you'd like for

them to use the content from the ContentPlaceHolder control on the master page, simply click on the smart tag symbol (the small black arrow in the upper-right corner of the control) and choose *Default to Masters Content* from the smart tag as shown in **figure 8**. When you do so, the menu item changes to *Create Custom Content*. Clicking it at that point removes the content from the master page allowing you to define custom content for that particular Content control.

Figure 7: Setting a Content Control to Default to the Master Pages Content

Connecting Master Page and Content Pages

The association between a master page and a content page can be configured in one of four different ways:

- The **MasterPageFile** attribute of the @Page directive
- Setting the **Page.MasterPageFile** property in code.
- The **<pages>** element in the applications configuration file (web.config in the root folder of the application)
- The **<pages>** element in a subfolders configuration file (web.config in a subfolder)

MasterPageFile Attribute

The MasterPageFile attribute makes it easy to apply a master page to a particular ASP.NET page. It is also the method used to apply the master page when you check the **Select Master Page** checkbox as you did in Exercise 1.

Setting Page.MasterPageFile in Code

By setting the MasterPageFile property in code, you can apply a particular master page to your content at runtime. This is useful in cases where you may need to apply a specific master page based upon a users role or some other criteria. The MasterPageFile property must be set in the PreInit method. If it is set after the PreInit method, an InvalidOperationException will be thrown. The page on which this property is being set must also have a Content control as the top-level control for the page. Otherwise an HttpException will be thrown when the MasterPageFile property is set.

Using the <pages> Element

You can configure a master page for your pages by setting the masterPageFile attribute in the <pages> element of the web.config file. When using this method, keep in mind that web.config files lower in the application structure can override this setting. Any MasterPageFile attribute set in a @Page directive will also override this setting. Using the <pages> element makes it simple to create a *master* master page that can be overridden if necessary in particular folders or files.

Properties in Master Pages

A master page can expose properties by simply making those properties public within the master page. For example, the following code defines a property called SomeProperty:

```
private string _SomeProperty; public string SomeProperty { get { return _SomeProperty; } set { _SomeProperty =
value; } }
```

To access the SomeProperty property from the Content page, you will need to use the Master property like so:

```
void Page_Load() { Master.SomeProperty = "Master Page Property"; }
```

Nesting Master Pages

Master pages are the perfect solution for ensuring a common look and feel across a large Web application. However, it's not uncommon to have certain parts of a large site share a common interface while other parts share a different interface. To address that need, multiple master pages are the perfect solution. However, that still doesn't address the fact that a large application may have certain components (such as a menu, for example) that are shared among all pages and other components that are shared only among certain sections of the site. For that type of situation, nested master pages fill the need nicely. As you've seen, a normal master page consists of a master page and a content page. In a nested master page situation, there are two master pages; a parent master and a child master. The child master page is also a content page and its master is the parent master page.

Here is the code for a typical master page:

```
<%@ Master Language="C#" AutoEventWireup="true" CodeFile="parent.master.cs" Inherits="parent" %> <!DOCTYPE
html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd"> <html xmlns="http://www.w3.org/1999/xhtml" > <head runat="server"> <title>Typical Master
Page</title> </head> <body> <form id="form1" runat="server"> <div> <asp:contentplaceholder
id="MainMenuContent" runat="server" /> </div> </form> </body> </html>
```

In a nested master scenario, this would be the parent master. Another master page would use this page as its master page, and that code would look like this:

```
<%@ Master Language="C#" MasterPageFile="~/parent.master" AutoEventWireup="true" CodeFile="child.master.cs"
Inherits="child" %> <asp:Content ID="Content1" ContentPlaceHolderID="MainMenuContent" Runat="Server">
<span>From the Child Master.</span> <asp:contentplaceholder id="ChildPlaceHolder1" runat="server" />
</asp:Content>
```

Note that in this scenario, the child master is also a content page for the parent master. All of the child master's content appears inside of a Content control that gets its content from the parent's ContentPlaceHolder control.

> **NOTE**
> Designer support is not available for nested master pages. When you are developing using nested masters, you will need to use source view.

This video shows a walkthrough of using nested master pages.

Figure 8: Selecting a Master Page

Data Source Controls

4/10/2020 • 22 minutes to read • Edit Online

by Microsoft

> The DataGrid control in ASP.NET 1.x marked a great improvement in data access in Web applications. However, it wasn't as user-friendly as it could have been. It still required a considerable amount of code to obtain much useful functionality from it. Such is the model in all data access endeavors in 1.x.

The DataGrid control in ASP.NET 1.x marked a great improvement in data access in Web applications. However, it wasn't as user-friendly as it could have been. It still required a considerable amount of code to obtain much useful functionality from it. Such is the model in all data access endeavors in 1.x.

ASP.NET 2.0 addresses this with in part with data source controls. The data source controls in ASP.NET 2.0 provide developers with a declarative model for retrieving data, displaying data, and editing data. The purpose of data source controls is to provide a consistent representation of data to data-bound controls regardless of the source of those data. At the heart of the data source controls in ASP.NET 2.0 is the DataSourceControl abstract class. The DataSourceControl class provides a base implementation of the IDataSource interface and the IListSource interface, the latter of which allows you to assign the data source control as the DataSource of a data-bound control (via the new DataSourceId property discussed later) and expose the data therein as a list. Each list of data from a data source control is exposed as a DataSourceView object. Access to the DataSourceView instances is provided by the IDataSource interface. For example, the GetViewNames method returns an ICollection that allows you to enumerate the DataSourceViews associated with a particular data source control, and the GetView method allows you to access a particular DataSourceView instance by name.

Data source controls have no user-interface. They are implemented as server controls so that they can support declarative syntax and so that they have access to page state if desired. Data source controls do not render any HTML markup to the client.

> **NOTE**
>
> As you'll see later, there are also caching benefits obtained by using data source controls.

Storing Connection Strings

Before we get into looking at how to configure data source controls, we should cover a new capability in ASP.NET 2.0 concerning connection strings. ASP.NET 2.0 introduces a new section in the configuration file that allows you to easily store connection strings that can be read dynamically at runtime. The <connectionStrings> section makes it easy to store connection strings.

The snippet below adds a new connection string.

```
<connectionStrings> <add name="Northwind" connectionString="Data Source=localhost; Integrated
Security=SSPI;Initial Catalog=Northwind;" providerName="System.Data.SqlClient" /> </connectionStrings>
```

> **NOTE**
> Just as with the <appSettings> section, the <connectionStrings> section appears outside of the <system.web> section in the configuration file.

To use this connection string, you can use the following syntax when setting the ConnectionString attribute of a server control.

```
ConnectionString="<%$ ConnectionStrings:Northwind%>"
```

The <connectionStrings> section can also be encrypted so that sensitive information is not exposed. That ability will be covered in a later module.

Caching Data Sources

Each DataSourceControl provides four properties for configuring caching; EnableCaching, CacheDuration, CacheExpirationPolicy, and CacheKeyDependency.

EnableCaching

EnableCaching is a Boolean property that determines whether or not caching is enabled for the data source control.

CacheDuration Property

The CacheDuration property sets the number of seconds that the cache remains valid. Setting this property to **0** causes the cache to remain valid until explicitly invalidated.

CacheExpirationPolicy Property

The CacheExpirationPolicy property can be set to either **Absolute** or **Sliding**. Setting it to Absolute means that the maximum amount of time that the data will be cached is the number of seconds specified by the CacheDuration property. By setting it to Sliding, the expiration time is reset when each operation is performed.

CacheKeyDependency Property

If a string value is specified for the CacheKeyDependency property, ASP.NET will set up a new cache dependency based on that string. This allows you to explicitly invalidate the cache by simply changing or removing the CacheKeyDependency.

Important: If impersonation is enabled and access to the data source and/or content of data are based upon client identity, it is recommended that caching be disabled by setting EnableCaching to False. If caching is enabled in this scenario and a user other than the user who originally requested the data issues a request, authorization to the data source is not enforced. The data will simply be served from cache.

The SqlDataSource Control

The SqlDataSource control allows a developer to access data stored in any relational database that supports ADO.NET. It can use the System.Data.SqlClient provider to access a SQL Server database, the System.Data.OleDb provider, the System.Data.Odbc provider, or the System.Data.OracleClient provider to access Oracle. Therefore, the SqlDataSource is certainly not only used for accessing data in a SQL Server database.

In order to use the SqlDataSource, you simply provide a value for the ConnectionString property and specify a

SQL command or stored procedure. The SqlDataSource control takes care of working with the underlying ADO.NET architecture. It opens the connection, queries the data source or executes the stored procedure, returns the data, and then closes the connection for you.

> **NOTE**
> Because the DataSourceControl class automatically closes the connection for you, it should reduce the number of customer calls generated by leaking database connections.

The code snippet below binds a DropDownList control to a SqlDataSource control using the connection string that is stored in the configuration file as shown above.

```
<asp:SqlDataSource id="SqlDataSource1" runat="server" DataSourceMode="DataReader" ConnectionString="<%$
ConnectionStrings:Northwind%>" SelectCommand="SELECT EmployeeID, LastName FROM Employees">
</asp:SqlDataSource><asp:DropDownList id="ListBox1" runat="server" DataTextField="LastName"
DataValueField="EmployeeID" DataSourceID="SqlDataSource1"> </asp:DropDownList>
```

As illustrated above, the DataSourceMode property of the SqlDataSource specifies the mode for the data source. In the example above, the DataSourceMode is set to DataReader. In that case, the SqlDataSource will return an IDataReader object using a forward-only and read-only cursor. The specified type of object that is returned is controlled by the provider that is used. In this case, I'm using the System.Data.SqlClient provider as specified in the <connectionStrings> section of the web.config file. Therefore, the object that is returned will be of type SqlDataReader. By specifying a DataSourceMode value of DataSet, the data can be stored in a DataSet on the server. This mode allows you to add features such as sorting, paging, etc. If I had been data-binding the SqlDataSource to a GridView control, I would have chosen the DataSet mode. However, in the case of a DropDownList, the DataReader mode is the correct choice.

> **NOTE**
> When caching a SqlDataSource or an AccessDataSource, the DataSourceMode property must be set to DataSet. An exception will occur if you enable caching with a DataSourceMode of DataReader.

SqlDataSource Properties

The following are some of the properties of the SqlDataSource control.

CancelSelectOnNullParameter

A Boolean value that specifies whether a select command is canceled if one of the parameters is null. True by default.

ConflictDetection

In a situation where multiple users may be updating a data source at the same time, the ConflictDetection property determines the behavior of the SqlDataSource control. This property evaluates to one of the values of the ConflictOptions enumeration. Those values are **CompareAllValues** and **OverwriteChanges**. If set to OverwriteChanges, the last person to write data to the data source overwrites any previous changes. However, if the ConflictDetection property is set to CompareAllValues, parameters get created for the columns returned by the SelectCommand and parameters are also created to hold the original values in each of those columns allowing the SqlDataSource to determine whether or not the values have changed since the SelectCommand was executed.

DeleteCommand

Sets or gets the SQL string used when deleting rows from the database. This can either be a SQL query or a stored procedure name.

DeleteCommandType

Sets or gets the type of delete command, either a SQL query (Text) or a stored procedure (StoredProcedure).

DeleteParameters

Returns the parameters that are used by the DeleteCommand of the SqlDataSourceView object associated with the SqlDataSource control.

OldValuesParameterFormatString

This property is used to specify the format of the original value parameters in cases where the ConflictDetection property is set to CompareAllValues. The default is {0} which means that original value parameters will take the same name as the original parameter. In other words, if the field name is EmployeeID, the original value parameter would be @EmployeeID.

SelectCommand

Sets or gets the SQL string that is used to retrieve data from the database. This can either be a SQL query or a stored procedure name.

SelectCommandType

Sets or gets the type of select command, either a SQL query (Text) or a stored procedure (StoredProcedure).

SelectParameters

Returns the parameters that are used by the SelectCommand of the SqlDataSourceView object associated with the SqlDataSource control.

SortParameterName

Gets or sets the name of a stored procedure parameter that is used when sorting data retrieved by the data source control. Valid only when SelectCommandType is set to StoredProcedure.

SqlCacheDependency

A semi-colon delimited string specifying the databases and tables used in a SQL Server cache dependency. (SQL cache dependencies will be discussed in a later module.)

UpdateCommand

Sets or gets the SQL string that is used when updating data in the database. This can either be a SQL query or a stored procedure name.

UpdateCommandType

Sets or gets the type of update command, either a SQL query (Text) or a stored procedure (StoredProcedure).

UpdateParameters

Returns the parameters that are used by the UpdateCommand of the SqlDataSourceView object associated with the SqlDataSource control.

The AccessDataSource Control

The AccessDataSource control derives from the SqlDataSource class and is used to data-bind to a Microsoft Access database. The ConnectionString property for the AccessDataSource control is a read-only property. Instead of using the ConnectionString property, the DataFile property is used to point to the Access Database as shown below.

```
<asp:AccessDataSource id="AccessDataSource1" runat="server" DataFile="~/App_Data/Northwind.mdb">
</asp:AccessDataSource>
```

The AccessDataSource will always set the ProviderName of the base SqlDataSource to System.Data.OleDb and

connects to the database using the Microsoft.Jet.OLEDB.4.0 OLE DB provider. You cannot use the AccessDataSource control to connect to a password-protected Access database. If you have to connect to a password protected database, you should use the SqlDataSource control.

> **NOTE**
> Access databases stored within the Web site should be placed in the App_Data directory. ASP.NET does not allow files in this directory to be browsed. You will need to grant the process account Read and Write permissions to the App_Data directory when using Access databases.

The XmlDataSource Control

The XmlDataSource is used to data-bind XML data to data-bound controls. You can bind to an XML file using the DataFile property or you can bind to an XML string using the Data property. The XmlDataSource exposes XML attributes as bindable fields. In cases where you need to bind to values that are not represented as attributes, you will need to use an XSL transform. You can also use XPath expressions to filter XML data.

Consider the following XML file:

```
<?xml version="1.0" encoding="utf-8" ?> <People> <Person FirstName="Jake" LastName="Stone"> <Address>
<Street>345 Maple St.</Street> <City>Redmond</City> <Region>WA</Region> <ZipCode>01434</ZipCode> </Address>
<Job> <Title>CEO</Title> <Description>Develops company strategies.</Description> </Job> </Person> <Person
FirstName="Jacob" LastName="Ladder"> <Address> <Street>123 Elm St.</Street> <City>Seattle</City>

</People>
```

Notice that the XmlDataSource uses an XPath property of *People/Person* in order to filter on just the <Person> nodes. The DropDownList then data-binds to the LastName attribute using the DataTextField property.

While the XmlDataSource control is primarily used to data-bind to read-only XML data, it is possible to edit the XML data file. Note that in such cases, automatic insertion, updating, and deletion of information in the XML file does not happen automatically as it does with other data source controls. Instead, you will have to write code to manually edit the data using the following methods of the XmlDataSource control.

GetXmlDocument

Retrieves an XmlDocument object containing the XML code retrieved by the XmlDataSource.

Save

Saves the in-memory XmlDocument back to the data source.

It's important to realize that the Save method will only work when the following two conditions are met:

1. The XmlDataSource is using the DataFile property to bind to an XML file instead of the Data property to bind to in-memory XML data.
2. No transformation is specified via the Transform or TransformFile property.

Note also that the Save method can yield unexpected results when called by multiple users concurrently.

The ObjectDataSource Control

The data source controls that we have covered up to this point are excellent choices for two-tier applications where the data source control communicates directly to the data store. However, many real-world applications are multi-tier applications where a data source control might need to communicate to a business object which, in turn,

communicates with the data layer. In these situations, the ObjectDataSource fills the bill nicely. The ObjectDataSource works in conjunction with a source object. The ObjectDataSource control will create an instance of the source object, call the specified method, and dispose of the object instance all within the scope of a single request, if your object has instance methods instead of static methods (Shared in Visual Basic). Therefore, your object must be stateless. That is, your object should acquire and release all required resources within the span of a single request. You can control how the source object is created by handling the ObjectCreating event of the ObjectDataSource control. You can create an instance of the source object, and then set the ObjectInstance property of the ObjectDataSourceEventArgs class to that instance. The ObjectDataSource control will use the instance that is created in the ObjectCreating event instead of creating an instance on its own.

If the source object for an ObjectDataSource control exposes public static methods (Shared in Visual Basic) that can be called to retrieve and modify data, an ObjectDataSource control will call those methods directly. If an ObjectDataSource control must create an instance of the source object in order to make method calls, the object must include a public constructor that takes no parameters. The ObjectDataSource control will call this constructor when it creates a new instance of the source object.

If the source object does not contain a public constructor without parameters, you can create an instance of the source object that will be used by the ObjectDataSource control in the ObjectCreating event.

Specifying Object Methods

The source object for an ObjectDataSource control can contain any number of methods that are used to select, insert, update, or delete data. These methods are called by the ObjectDataSource control based on the name of the method, as identified by using either the SelectMethod, InsertMethod, UpdateMethod, or DeleteMethod property of the ObjectDataSource control. The source object can also include an optional SelectCount method, which is identified by the ObjectDataSource control using the SelectCountMethod property, that returns the count of the total number of objects at the data source. The ObjectDataSource control will call the SelectCount method after a Select method has been called to retrieve the total number of records at the data source for use when paging.

Lab Using Data Source Controls

Exercise 1 - Displaying Data with the SqlDataSource Control

The following exercise uses the SqlDataSource control to connect to the Northwind database. It assumes that you have access to the Northwind database on a SQL Server 2000 instance.

1. Create a new ASP.NET Web site.
2. Add a new web.config file.
   a. Right-click on the project in Solution Explorer and click Add New Item.
   b. Choose Web Configuration File from the list of templates and click Add.
3. Edit the <connectionStrings> section as follows:

```
<asp:SqlDataSource ID="SqlDataSource1" runat="server"
    ConnectionString="<%$ConnectionStrings:Northwind%>"
    SelectCommand="SELECT * FROM Products">
</asp:SqlDataSource>
```

4. Switch to Code view and add a ConnectionString attribute and a SelectCommand attribute to the <asp:SqlDataSource> control as follows:

```
<asp:SqlDataSource ID="SqlDataSource1" runat="server"
    ConnectionString="<%$ConnectionStrings:Northwind%>"
    SelectCommand="SELECT * FROM Products">
</asp:SqlDataSource>
```

5. From Design view, add a new GridView control.
6. From the Choose Data Source dropdown in the GridView Tasks menu, choose SqlDataSource1.
7. Right-click on Default.aspx and choose View in Browser from the menu. Click Yes when prompted to save.
8. The GridView displays the data from the Products table.

Exercise 2 - Editing Data with the SqlDataSource Control

The following exercise demonstrates how to data bind a DropDownList control using the declarative syntax and allows you to edit the data presented in the DropDownList control.

1. In Design view, delete the GridView control from Default.aspx.

   Important: Leave the SqlDataSource control on the page.

2. Add a DropDownList control to Default.aspx.
3. Switch to Source view.
4. Add a DataSourceId, DataTextField, and DataValueField attribute to the <asp:DropDownList> control as follows:

```
<asp:DropDownList ID="ddlProducts" runat="server"
     DataSourceId="SqlDataSource1" DataTextField="ProductName"
     DataValueField="ProductID">
</asp:DropDownList>
```

5. Save Default.aspx and view it in the browser. Note that the DropDownList contains all of the products from the Northwind database.
6. Close the browser.
7. In Source view of Default.aspx, add a new TextBox control below the DropDownList control. Change the ID property of the TextBox to txtProductName.
8. Under the TextBox control, add a new Button control. Change the ID property of the Button to btnUpdate and the Text property to **Update Product Name**.
9. In Source view of Default.aspx, add an UpdateCommand property and two new UpdateParameters to the SqlDataSource tag as follows:

```
<asp:SqlDataSource ID="SqlDataSource1" runat="server"
    ConnectionString="<%$ConnectionStrings:Northwind%>"
    SelectCommand="SELECT * FROM Products"
    UpdateCommand="UPDATE Products SET ProductName=@ProductName WHERE ProductID=@ProductID">
      <UpdateParameters>
      <asp:ControlParameter Name="ProductName"
        ControlID="txtProductName" PropertyName="Text" />
      <asp:ControlParameter Name="ProductID"
        ControlID="ddlProducts" PropertyName="SelectedValue" />
</asp:SqlDataSource>
```

> **NOTE**
> Note that there are two update parameters (ProductName and ProductID) added in this code. These parameters are mapped to the Text property of the txtProductName TextBox and the SelectedValue property of the ddlProducts DropDownList.

10. Switch to Design view and double-click on the Button control to add an event handler.
11. Add the following code to the btnUpdate_Click code:

```
SqlDataSource1.Update();
```

12. Right-click on Default.aspx and choose to view it in the browser. Click Yes when prompted to save all changes.
13. ASP.NET 2.0 partial classes allow for compilation at runtime. It is not necessary to build an application in order to see code changes take effect.
14. Select a product from the DropDownList.
15. Enter a new name for the selected product in the TextBox and then click the Update button.
16. The product name is updated in the database.

Exercise 3 Using the ObjectDataSource Control

This exercise will demonstrate how to use the ObjectDataSource control and a source object to interact with the Northwind database.

1. Right-click on the project in Solution Explorer and click on Add New Item.
2. Select Web Form in the templates list. Change the name to object.aspx and click Add.
3. Right-click on the project in Solution Explorer and click on Add New Item.
4. Select Class in the templates list. Change the name of the class to NorthwindData.cs and click Add.
5. Click Yes when prompted to add the class to the App_Code folder.
6. Add the following code to the NorthwindData.cs file:

```
using System;
using System.Data;
using System.Configuration;
using System.Web;
using System.Web.Security;
using System.Web.UI;
using System.Web.UI.WebControls;
using System.Web.UI.WebControls.WebParts;
using System.Web.UI.HtmlControls;
using System.Data.SqlClient;
public class NorthwindData {
    private string _connectionString;
    public NorthwindData() {
        Initialize();
    }

    private void Initialize() {
        if (ConfigurationManager.ConnectionStrings["Northwind"] == null ||
            ConfigurationManager.ConnectionStrings["Northwind"].ConnectionString.Trim() == "") {
                throw new Exception("A connection string named 'Northwind' with " +
```

```
                "a valid connection string must exist in the <connectionStrings> " +
                "configuration section for the application.");
        }
        _connectionString = ConfigurationManager.ConnectionStrings["Northwind"].ConnectionString;
    }

    public DataTable GetAllEmployees(string sortColumns, int startRecord, int maxRecords) {
        VerifySortColumns(sortColumns);
        string sqlCmd = "SELECT EmployeeID, LastName, FirstName, Address, " +
            "City, Region, PostalCode FROM Employees ";
        if (sortColumns.Trim() == "")
            sqlCmd += "ORDER BY EmployeeID";
        else
            sqlCmd += "ORDER BY " + sortColumns;

        SqlConnection conn = new SqlConnection(_connectionString);
        SqlDataAdapter da = new SqlDataAdapter(sqlCmd, conn);
        DataSet ds = new DataSet();
        try {
            conn.Open();
            da.Fill(ds, startRecord, maxRecords, "Employees");
        } catch (SqlException e) {
            // Handle exception.
        } finally {
            conn.Close();
        }
        return ds.Tables["Employees"];
    }

Data Bound Controls

4/10/2020 • 52 minutes to read • Edit Online

by Microsoft

Most ASP.NET applications rely on some degree of data presentation from a back-end data source. Data-bound controls have been a pivotal part of interacting with data in dynamic Web applications. ASP.NET 2.0 introduces some substantial improvements to data-bound controls, including a new BaseDataBoundControl class and declarative syntax.

Most ASP.NET applications rely on some degree of data presentation from a back-end data source. Data-bound controls have been a pivotal part of interacting with data in dynamic Web applications. ASP.NET 2.0 introduces some substantial improvements to data-bound controls, including a new BaseDataBoundControl class and declarative syntax.

The BaseDataBoundControl acts as the base class for the DataBoundControl class and the HierarchicalDataBoundControl class. In this module, we will discuss the following classes that derive from DataBoundControl:

- AdRotator
- List controls
- GridView
- FormView
- DetailsView

We will also discuss the following classes that derive from HierarchicalDataBoundControl class:

- TreeView
- Menu
- SiteMapPath

DataBoundControl Class

The DataBoundControl class is an abstract class (marked MustInherit in VB) used to interact with tabular or list-style data. The following controls are some of the controls that derive from DataBoundControl.

AdRotator

The AdRotator control allows you to display a graphic banner on a Web page that is linked to a specific URL. The graphic that is displayed is rotated using properties for the control. The frequency of a particular ad displaying on a page can be configured using the **Impressions** property and ads can be filtered using keyword filtering.

AdRotator controls use either an XML file or a table in a database for data. The following attributes are used in XML files to configure the AdRotator control.

ImageUrl

The URL of an image to display for the ad.

NavigateUrl

The URL that the user should be taken to when the ad is clicked. This should be URL encoded.

AlternateText

The alternate text that is displayed in a tooltip and read by screen readers. Also displays when the image specified by ImageUrl is not available.

Keyword

Defines a keyword that can be used when using keyword filtering. If specified, only those ads with a keyword matching the keyword filter will be displayed.

Impressions

A weighting number that determines how often a particular ad is likely to appear. It is relative to the impression of other ads in the same file. The maximum value of the collective impressions for all ads in an XML file is 2,048,000,000 1.

Height

The height of the ad in pixels.

Width

The width of the ad in pixels.

> **NOTE**
>
> The Height and Width attributes override the height and width for the AdRotator control itself.

A typical XML file might look like the following:

```
<?xml version="1.0" encoding="utf-8" ?> <Advertisements xmlns="http://schemas.microsoft.com/AspNet/AdRotator-Schedule-File"> <Ad> <ImageUrl>~/images/Contoso_ad.gif</ImageUrl> <NavigateUrl>http://www.contoso-ltd.com</NavigateUrl> <AlternateText>Ad for Contoso, Ltd. Web site</AlternateText> <Impressions>100</Impressions> </Ad> <Ad> <ImageUrl>~/images/Aspnet_ad.gif</ImageUrl> <NavigateUrl>http://www.asp.net</NavigateUrl> <AlternateText>Ad for ASP.NET Web site</AlternateText> <Impressions>50</Impressions> </Ad> </Advertisements>
```

In the above example, the ad for Contoso is twice as likely to appear as the ad for the ASP.NET Web site because of the value for the Impressions attribute.

To display ads from the above XML file, add an AdRotator control to a page and set the **AdvertisementFile** property to point to the XML file as shown below:

```
<asp:AdRotator ID="AdRotator1" runat="server" AdvertisementFile="App_Data/Ads.xml" />
```

If you choose to use a database table as the data source for your AdRotator control, you will first need to set up a database using the following schema:

COLUMN NAME	DATA TYPE	DESCRIPTION
ID	int	Primary key. This column can have any name.
ImageUrl	nvarchar(*length*)	The relative or absolute URL of the image to display for the ad.
NavigateUrl	nvarchar(*length*)	The target URL for the ad. If you do not provide a value, the ad is not a hyperlink.

COLUMN NAME	DATA TYPE	DESCRIPTION
AlternateText	nvarchar(*length*)	The text displayed if the image cannot be found. In some browsers, the text is displayed as a ToolTip. Alternate text is also used for accessibility so that users who cannot see the graphic can hear its description read out loud.
Keyword	nvarchar(*length*)	A category for the ad on which the page can filter.
Impressions	int(4)	A number that indicates the likelihood of how often the ad is displayed. The larger the number, the more often the ad will be displayed. The total of all impressions values in the XML file may not exceed 2,048,000,000 - 1.
Width	int(4)	The width of the image in pixels.
Height	int(4)	The height of the image in pixels.

In cases where you already have a database with a different schema, you can use the **AlternateTextField**, **ImageUrlField**, and **NavigateUrlField** properties to map the AdRotator attributes to your existing database. To display the data from the database in the AdRotator control, add a data source control to the page, configure the connection string for the data source control to point to your database, and set the AdRotator control's **DataSourceID** property to the ID of the data source control. In cases where you have a need to configure AdRotator ads programmatically, use the AdCreated event. The AdCreated event takes two parameters; one an object, and the other an instance of AdCreatedEventArgs. The AdCreatedEventArgs is a reference to the ad that is being created.

The following code snippet sets the ImageUrl, NavigateUrl, and AlternateText for an ad programmatically:

```
protected void AdRotator1_AdCreated(object sender, System.Web.UI.WebControls.AdCreatedEventArgs e) {
e.ImageUrl = "images/contoso_ad.gif"; e.NavigateUrl = "http://www.contoso-ltd.com/"; e.AlternateText = "Ad for
Contoso, Ltd Web site"; }
```

List Controls

List controls include the ListBox, DropDownList, CheckBoxList, RadioButtonList, and BulletedList. Each of these controls can be data bound to a data source. They use one field in the data source as the display text and can optionally use a second field as the value of an item. Items can also be added statically at design-time, and you can mix static items and dynamic items added from a data source.

To data bind a list control, add a data source control to the page. Specify a SELECT command for the data source control and then set the DataSourceID property of the list control to the ID of the data source control. Use the **DataTextField** and **DataValueField** properties to define the display text and the value for the control. Additionally, you can use the **DataTextFormatString** property to control the appearance of the display text as follows:

EXPRESSION	DESCRIPTION

EXPRESSION	DESCRIPTION
Price: {0:C}	For numeric/decimal data. Displays the literal "Price:" followed by numbers in currency format. The currency format depends on the culture setting specified in the culture attribute on the **Page** directive or in the Web.config file.
{0:D4}	For integer data. Cannot be used with decimal numbers. Integers are displayed in a zero-padded field that is four characters wide.
{0:N2}%	For numeric data. Displays the number with 2-decimal place precision followed by the literal "%".
{0:000.0}	For numeric/decimal data. Numbers are rounded to one decimal place. Numbers less than three digits are zero-padded.
{0:D}	For date/time data. Displays long date format ("Thursday, August 06, 1996"). Date format depends on the culture setting of the page or the Web.config file.
{0:d}	For date/time data. Displays short date format ("12/31/99").
{0:yy-MM-dd}	For date/time data. Displays date in numeric year-month-day format (96-08-06)

GridView

The GridView control allows for tabular data display and editing using a declarative approach and is the successor to the DataGrid control. The following features are available in the GridView control.

- Binding to data source controls, such as SqlDataSource.
- Built-in sorting capabilities.
- Built-in updating and deleting capabilities.
- Built-in paging capabilities.
- Built-in row selection capabilities.
- Programmatic access to the GridView object model to dynamically set properties, handle events, and so on.
- Multiple key fields.
- Multiple data fields for the hyperlink columns.
- Customizable appearance through themes and styles.

Column Fields

Each column in the GridView control is represented by a DataControlField object. By default, the AutoGenerateColumns property is set to **true**, which creates an AutoGeneratedField object for each field in the data source. Each field is then rendered as a column in the GridView control in the order that each field appears in the data source. You can also manually control which column fields appear in the **GridView** control by setting the **AutoGenerateColumns** property to **false** and then defining your own column field collection. Different column field types determine the behavior of the columns in the control.

The following table lists the different column field types that can be used.

COLUMN FIELD TYPE	DESCRIPTION
BoundField	Displays the value of a field in a data source. This is the default column type of the GridView control.
ButtonField	Displays a command button for each item in the GridView control. This allows you to create a column of custom button controls, such as the Add or the Remove button.
CheckBoxField	Displays a check box for each item in the GridView control. This column field type is commonly used to display fields with a Boolean value.
CommandField	Displays predefined command buttons to perform selecting, editing, or deleting operations.
HyperLinkField	Displays the value of a field in a data source as a hyperlink. This column field type allows you to bind a second field to the hyperlink's URL.
ImageField	Displays an image for each item in the GridView control.
TemplateField	Displays user-defined content for each item in the GridView control according to a specified template. This column field type allows you to create a custom column field.

To define a column field collection declaratively, first add opening and closing **<Columns>** tags between the opening and closing tags of the GridView control. Next, list the column fields that you want to include between the opening and closing **<Columns>** tags. The columns specified are added to the Columns collection in the order listed. The **Columns** collection stores all the column fields in the control and allows you to programmatically manage the column fields in the GridView control.

Explicitly declared column fields can be displayed in combination with automatically generated column fields. When both are used, explicitly declared column fields are rendered first, followed by the automatically generated column fields.

Binding to Data

The GridView control can be bound to a data source control (such as **SqlDataSource**, **ObjectDataSource**, and so on), as well as any data source that implements the System.Collections.IEnumerable interface (such as System.Data.DataView, System.Collections.ArrayList, or System.Collections.Hashtable). Use one of the following methods to bind the GridView control to the appropriate data source type:

- To bind to a data source control, set the DataSourceID property of the GridView control to the ID value of the data source control. The GridView control automatically binds to the specified data source control and can take advantage of the data source control's capabilities to perform sorting, updating, deleting, and paging functionality. This is the preferred method to bind to data.
- To bind to a data source that implements the System.Collections.IEnumerable interface, programmatically set the DataSource property of the GridView control to the data source and then call the DataBind method. When using this method, the GridView control does not provide built-in sorting, updating, deleting, and paging functionality. You need to provide this functionality yourself.

Data Operations

The GridView control provides many built-in capabilities that allow the user to sort, update, delete, select, and page

through items in the control. When the GridView control is bound to a data source control, the GridView control can take advantage of the data source control's capabilities and provide automatic sorting, updating, and deleting functionality.

> **NOTE**
> The GridView control can provide support for sorting, updating, and deleting with other types of data sources; however, you will need to provide an appropriate event handler with the implementation for these operations.

Sorting allows the user to sort the items in the GridView control with respect to a specific column by clicking on the column's header. To enable sorting, set the AllowSorting property to **true**.

The automatic updating, deleting, and selection functionalities are enabled when a button in a **ButtonField** or **TemplateField** column field, with a command name of "Edit", "Delete", and "Select", respectively, is clicked. The GridView control can automatically add a **CommandField** column field with an Edit, Delete, or Select button if the AutoGenerateEditButton, AutoGenerateDeleteButton, or AutoGenerateSelectButton property is set to **true**, respectively.

> **NOTE**
> Inserting records into the data source is not directly supported by the GridView control. However, it is possible to insert records by using the GridView control in conjunction with the DetailsView or FormView control.

Instead of displaying all the records in the data source at the same time, the GridView control can automatically break the records up into pages. To enable paging, set the AllowPaging property to **true**.

Customizing the User Interface

You can customize the appearance of the GridView control by setting the style properties for the different parts of the control. The following table lists the different style properties.

STYLE PROPERTY	DESCRIPTION
AlternatingRowStyle	The style settings for the alternating data rows in the GridView control. When this property is set, the data rows are displayed alternating between the RowStyle settings and the **AlternatingRowStyle** settings.
EditRowStyle	The style settings for the row being edited in the GridView control.
EmptyDataRowStyle	The style settings for the empty data row displayed in the GridView control when the data source does not contain any records.
FooterStyle	The style settings for the footer row of the GridView control.
HeaderStyle	The style settings for the header row of the GridView control.
PagerStyle	The style settings for the pager row of the GridView control.

STYLE PROPERTY	DESCRIPTION
RowStyle	The style settings for the data rows in the GridView control. When the **AlternatingRowStyle** property is also set, the data rows are displayed alternating between the **RowStyle** settings and the **AlternatingRowStyle** settings.
SelectedRowStyle	The style settings for the selected row in the GridView control.

You can also show or hide different parts of the control. The following table lists the properties that control which parts are shown or hidden.

PROPERTY	DESCRIPTION
ShowFooter	Shows or hides the footer section of the GridView control.
ShowHeader	Shows or hides the header section of the GridView control.

Events

The GridView control provides several events that you can program against. This allows you to run a custom routine whenever an event occurs. The following table lists the events supported by the GridView control.

EVENT	DESCRIPTION
PageIndexChanged	Occurs when one of the pager buttons is clicked, but after the GridView control handles the paging operation. This event is commonly used when you need to perform a task after the user navigates to a different page in the control.
PageIndexChanging	Occurs when one of the pager buttons is clicked, but before the GridView control handles the paging operation. This event is often used to cancel the paging operation.
RowCancelingEdit	Occurs when a row's Cancel button is clicked, but before the GridView control exits edit mode. This event is often used to stop the canceling operation.
RowCommand	Occurs when a button is clicked in the GridView control. This event is often used to perform a task when a button is clicked in the control.
RowCreated	Occurs when a new row is created in the GridView control. This event is often used to modify the contents of a row when the row is created.
RowDataBound	Occurs when a data row is bound to data in the GridView control. This event is often used to modify the contents of a row when the row is bound to data.
RowDeleted	Occurs when a row's Delete button is clicked, but after the GridView control deletes the record from the data source. This event is often used to check the results of the delete operation.

EVENT	DESCRIPTION
RowDeleting	Occurs when a row's Delete button is clicked, but before the GridView control deletes the record from the data source. This event is often used to cancel the deleting operation.
RowEditing	Occurs when a row's Edit button is clicked, but before the GridView control enters edit mode. This event is often used to cancel the editing operation.
RowUpdated	Occurs when a row's Update button is clicked, but after the GridView control updates the row. This event is often used to check the results of the update operation.
RowUpdating	Occurs when a row's Update button is clicked, but before the GridView control updates the row. This event is often used to cancel the updating operation.
SelectedIndexChanged	Occurs when a row's Select button is clicked, but after the GridView control handles the select operation. This event is often used to perform a task after a row is selected in the control.
SelectedIndexChanging	Occurs when a row's Select button is clicked, but before the GridView control handles the select operation. This event is often used to cancel the selection operation.
Sorted	Occurs when the hyperlink to sort a column is clicked, but after the GridView control handles the sort operation. This event is commonly used to perform a task after the user clicks on a hyperlink to sort a column.
Sorting	Occurs when the hyperlink to sort a column is clicked, but before the GridView control handles the sort operation. This event is often used to cancel the sorting operation or to perform a custom sorting routine.

FormView

The FormView control is used to display a single record from a data source. It is similar to the DetailsView control, except it displays user-defined templates instead of row fields. Creating your own templates gives you greater flexibility in controlling how the data is displayed. The FormView control supports the following features:

- Binding to data source controls, such as SqlDataSource and ObjectDataSource.
- Built-in inserting capabilities.
- Built-in updating and deleting capabilities.
- Built-in paging capabilities.
- Programmatic access to the FormView object model to dynamically set properties, handle events, and so on.
- Customizable appearance through user-defined templates, themes, and styles.

Templates

For the FormView control to display content, you need to create templates for the different parts of the control. Most templates are optional; however, you must create a template for the mode in which the control is configured. For example, a FormView control that supports inserting records must have an insert item template defined. The following table lists the different templates that you can create.

TEMPLATE TYPE	DESCRIPTION
EditItemTemplate	Defines the content for the data row when the FormView control is in edit mode. This template usually contains input controls and command buttons with which the user can edit an existing record.
EmptyDataTemplate	Defines the content for the empty data row displayed when the FormView control is bound to a data source that does not contain any records. This template usually contains content to alert the user that the data source does not contain any records.
FooterTemplate	Defines the content for the footer row. This template usually contains any additional content you would like to display in the footer row. As an alternative, you can simply specify text to display in the footer row by setting the FooterText property.
HeaderTemplate	Defines the content for the header row. This template usually contains any additional content you would like to display in the header row. As an alternative, you can simply specify text to display in the header row by setting the HeaderText property.
ItemTemplate	Defines the content for the data row when the FormView control is in read-only mode. This template usually contains content to display the values of an existing record.
InsertItemTemplate	Defines the content for the data row when the FormView control is in insert mode. This template usually contains input controls and command buttons with which the user can add a new record.
PagerTemplate	Defines the content for the pager row displayed when the paging feature is enabled (when the AllowPaging property is set to **true**). This template usually contains controls with which the user can navigate to another record.

Input controls in the edit item template and insert item template can be bound to the fields of a data source by using a two-way binding expression. This allows the FormView control to automatically extract the values of the input control for an update or insert operation. Two-way binding expressions also allow input controls in an edit item template to automatically display the original field values.

Binding to Data

The FormView control can be bound to a data source control (such as **SqlDataSource**, AccessDataSource, **ObjectDataSource** and so on), or to any data source that implements the System.Collections.IEnumerable interface (such as System.Data.DataView, System.Collections.ArrayList, and System.Collections.Hashtable). Use one of the following methods to bind the FormView control to the appropriate data source type:

- To bind to a data source control, set the DataSourceID property of the FormView control to the ID value of the data source control. The FormView control automatically binds to the specified data source control and can take advantage of the data source control's capabilities to perform inserting, updating, deleting, and paging functionality. This is the preferred method to bind to data.
- To bind to a data source that implements the **System.Collections.IEnumerable** interface, programmatically set the DataSource property of the FormView control to the data source and then call the DataBind method.

When using this method, the FormView control does not provide built-in inserting, updating, deleting, and paging functionality. You need to provide this functionality by using the appropriate event.

Data Operations

The FormView control provides many built-in capabilities that allow the user to update, delete, insert, and page through items in the control. When the FormView control is bound to a data source control, the FormView control can take advantage of the data source control's capabilities and provide automatic updating, deleting, inserting, and paging functionality. The FormView control can provide support for update, delete, insert, and paging operations with other types of data sources; however, you must provide an appropriate event handler with the implementation for these operations.

Because the FormView control uses templates, it does not provide a way to automatically generate command buttons to perform updating, deleting, or inserting operations. You must manually include these command buttons in the appropriate template. The FormView control recognizes certain buttons that have their **CommandName** properties set to specific values. The following table lists the command buttons that the FormView control recognizes.

BUTTON	COMMANDNAME VALUE	DESCRIPTION
Cancel	"Cancel"	Used in updating or inserting operations to cancel the operation and to discard the values entered by the user. The FormView control then returns to the mode specified by the DefaultMode property.
Delete	"Delete"	Used in deleting operations to delete the displayed record from the data source. Raises the ItemDeleting and ItemDeleted events.
Edit	"Edit"	Used in updating operations to put the FormView control in edit mode. The content specified in the **EditItemTemplate** property is displayed for the data row.
Insert	"Insert"	Used in inserting operations to attempt to insert a new record in the data source using the values provided by the user. Raises the ItemInserting and ItemInserted events.
New	"New"	Used in inserting operations to put the FormView control in insert mode. The content specified in the **InsertItemTemplate** property is displayed for the data row.

BUTTON	COMMANDNAME VALUE	DESCRIPTION
Page	"Page"	Used in paging operations to represent a button in the pager row that performs paging. To specify the paging operation, set the **CommandArgument** property of the button to "Next", "Prev", "First", "Last", or the index of the page to which to navigate. Raises the PageIndexChanging and PageIndexChanged events.
Update	"Update"	Used in updating operations to attempt to update the displayed record in the data source with the values provided by the user. Raises the ItemUpdating and ItemUpdated events.

Unlike the Delete button (which deletes the displayed record immediately), when the Edit or New button is clicked, the FormView control goes into edit or insert mode respectively. In edit mode, the content contained in the **EditItemTemplate** property is displayed for the current data item. Typically, the edit item template is defined such that the Edit button is replaced with an Update and a Cancel button. Input controls that are appropriate for the field's data type (such as a TextBox or a CheckBox control) are also usually displayed with a field's value for the user to modify. Clicking the Update button updates the record in the data source, while clicking the Cancel button abandons any changes.

Likewise, the content contained in the **InsertItemTemplate** property is displayed for the data item when the control is in insert mode. The insert item template is typically defined such that the New button is replaced with an Insert and a Cancel button, and empty input controls are displayed for the user to enter the values for the new record. Clicking the Insert button inserts the record in the data source, while clicking the Cancel button abandons any changes.

The FormView control provides a paging feature, which allows the user to navigate to other records in the data source. When enabled, a pager row is displayed in the FormView control that contains the page navigation controls. To enable paging, set the **AllowPaging** property to **true**. You can customize the pager row by setting the properties of objects contained in the PagerStyle and the PagerSettings property. Instead of using the built-in pager row UI, you can create your own UI by using the **PagerTemplate** property.

Customizing the User Interface

You can customize the appearance of the FormView control by setting the style properties for the different parts of the control. The following table lists the different style properties.

STYLE PROPERTY	DESCRIPTION
EditRowStyle	The style settings for the data row when the FormView control is in edit mode.
EmptyDataRowStyle	The style settings for the empty data row displayed in the FormView control when the data source does not contain any records.
FooterStyle	The style settings for the footer row of the FormView control.
HeaderStyle	The style settings for the header row of the FormView control.

STYLE PROPERTY	DESCRIPTION
InsertRowStyle	The style settings for the data row when the FormView control is in insert mode.
PagerStyle	The style settings for the pager row displayed in the FormView control when the paging feature is enabled.
RowStyle	The style settings for the data row when the FormView control is in read-only mode.

Events

The FormView control provides several events that you can program against. This allows you to run a custom routine whenever an event occurs. The following table lists the events supported by the FormView control.

EVENT	DESCRIPTION
ItemCommand	Occurs when a button within a FormView control is clicked. This event is often used to perform a task when a button is clicked in the control.
ItemCreated	Occurs after all FormViewRow objects are created in the FormView control. This event is often used to modify the values of a record before it is displayed.
ItemDeleted	Occurs when a Delete button (a button with its **CommandName** property set to "Delete") is clicked, but after the FormView control deletes the record from the data source. This event is often used to check the results of the delete operation.
ItemDeleting	Occurs when a Delete button is clicked, but before the FormView control deletes the record from the data source. This event is often used to cancel the delete operation.
ItemInserted	Occurs when an Insert button (a button with its **CommandName** property set to "Insert") is clicked, but after the FormView control inserts the record. This event is often used to check the results of the insert operation.
ItemInserting	Occurs when an Insert button is clicked, but before the FormView control inserts the record. This event is often used to cancel the insert operation.
ItemUpdated	Occurs when an Update button (a button with its **CommandName** property set to "Update") is clicked, but after the FormView control updates the row. This event is often used to check the results of the update operation.
ItemUpdating	Occurs when an Update button is clicked, but before the FormView control updates the record. This event is often used to cancel the update operation.

EVENT	DESCRIPTION
ModeChanged	Occurs after the FormView control changes modes (to edit, insert, or read-only mode). This event is often used to perform a task when the FormView control changes modes.
ModeChanging	Occurs before the FormView control changes modes (to edit, insert, or read-only mode). This event is often used to cancel a mode change.
PageIndexChanged	Occurs when one of the pager buttons is clicked, but after the FormView control handles the paging operation. This event is commonly used when you need to perform a task after the user navigates to a different record in the control.
PageIndexChanging	Occurs when one of the pager buttons is clicked, but before the FormView control handles the paging operation. This event is often used to cancel the paging operation.

DetailsView

The DetailsView control is used to display a single record from a data source in a table, where each field of the record is displayed in a row of the table. It can be used in combination with a GridView control for master-detail scenarios. The DetailsView control supports the following features:

- Binding to data source controls, such as SqlDataSource.
- Built-in inserting capabilities.
- Built-in updating and deleting capabilities.
- Built-in paging capabilities.
- Programmatic access to the DetailsView object model to dynamically set properties, handle events, and so on.
- Customizable appearance through themes and styles.

Row Fields

Each data row in the DetailsView control is created by declaring a field control. Different row field types determine the behavior of the rows in the control. Field controls derive from DataControlField. The following table lists the different row field types that can be used.

COLUMN FIELD TYPE	DESCRIPTION
BoundField	Displays the value of a field in a data source as text.
ButtonField	Displays a command button in the DetailsView control. This allows you to display a row with a custom button control, such as an Add or a Remove button.
CheckBoxField	Displays a check box in the DetailsView control. This row field type is commonly used to display fields with a Boolean value.
CommandField	Displays built-in command buttons to perform edit, insert, or delete operations in the DetailsView control.

COLUMN FIELD TYPE	DESCRIPTION
HyperLinkField	Displays the value of a field in a data source as a hyperlink. This row field type allows you to bind a second field to the hyperlink's URL.
ImageField	Displays an image in the DetailsView control.
TemplateField	Displays user-defined content for a row in the DetailsView control according to a specified template. This row field type allows you to create a custom row field.

By default, the AutoGenerateRows property is set to **true**, which automatically generates a bound row field object for each field of a bindable type in the data source. Valid bindable types are String, DateTime, Decimal, Guid, and the set of primitive types. Each field is then displayed in a row as text, in the order in which each field appears in the data source.

Automatically generating the rows provides a quick and easy way to display every field in the record. However, to make use of the DetailsView control's advanced capabilities you must explicitly declare the row fields to include in the DetailsView control. To declare the row fields, first set the **AutoGenerateRows** property to **false**. Next, add opening and closing **<Fields>** tags between the opening and closing tags of the DetailsView control. Finally, list the row fields that you want to include between the opening and closing **<Fields>** tags. The row fields specified are added to the Fields collection in the order listed. The **Fields** collection allows you to programmatically manage the row fields in the DetailsView control.

> **NOTE**
> Automatically generated row fields are not added to the Fields collection.

Binding to Data

The DetailsView control can be bound to a data source control, such as **SqlDataSource** or AccessDataSource, or to any data source that implements the System.Collections.IEnumerable interface, such as System.Data.DataView, System.Collections.ArrayList and System.Collections.Hashtable.

Use one of the following methods to bind the DetailsView control to the appropriate data source type:

- To bind to a data source control, set the DataSourceID property of the DetailsView control to the ID value of the data source control. The DetailsView control automatically binds to the specified data source control. This is the preferred method to bind to data.
- To bind to a data source that implements the **System.Collections.IEnumerable** interface, programmatically set the DataSource property of the DetailsView control to the data source and then call the DataBind method.

Security

This control can be used to display user input, which might include malicious client script. Check any information that is sent from a client for executable script, SQL statements, or other code before displaying it in your application. ASP.NET provides an input request validation feature to block script and HTML in user input.

Data Operations

The DetailsView control provides built-in capabilities that allow the user to update, delete, insert, and page through items in the control. When the DetailsView control is bound to a data source control, the DetailsView control can take advantage of the data source control's capabilities and provide automatic updating, deleting, inserting, and

paging functionality.

The DetailsView control can provide support for update, delete, insert, and paging operations with other types of data sources; however, you must provide the implementation for these operations in an appropriate event handler.

The DetailsView control can automatically add a **CommandField** row field with an Edit, Delete, or New button by setting the AutoGenerateEditButton, AutoGenerateDeleteButton, or AutoGenerateInsertButton properties to **true**, respectively. Unlike the Delete button (which deletes the selected record immediately), when the Edit or New button is clicked, the DetailsView control goes into edit or insert mode, respectively. In edit mode, the Edit button is replaced with an Update and a Cancel button. Input controls that are appropriate for the field's data type (such as a TextBox or a CheckBox control) are displayed with a field's value for the user to modify. Clicking the Update button updates the record in the data source, while clicking the Cancel button abandons any changes. Likewise, in insert mode, the New button is replaced with an Insert and a Cancel button, and empty input controls are displayed for the user to enter the values for the new record.

The DetailsView control provides a paging feature, which allows the user to navigate to other records in the data source. When enabled, page navigation controls are displayed in a pager row. To enable paging, set the AllowPaging property to **true**. The pager row can be customized using the PagerStyle and PagerSettings properties.

Customizing the User Interface

You can customize the appearance of the DetailsView control by setting the style properties for the different parts of the control. The following table lists the different style properties.

STYLE PROPERTY	DESCRIPTION
AlternatingRowStyle	The style settings for the alternating data rows in the DetailsView control. When this property is set, the data rows are displayed alternating between the RowStyle settings and the **AlternatingRowStyle** settings.
CommandRowStyle	The style settings for the row containing the built-in command buttons in the DetailsView control.
EditRowStyle	The style settings for the data rows when the DetailsView control is in edit mode.
EmptyDataRowStyle	The style settings for the empty data row displayed in the DetailsView control when the data source does not contain any records.
FooterStyle	The style settings for the footer row of the DetailsView control.
HeaderStyle	The style settings for the header row of the DetailsView control.
InsertRowStyle	The style settings for the data rows when the DetailsView control is in insert mode.
PagerStyle	The style settings for the pager row of the DetailsView control.

STYLE PROPERTY	DESCRIPTION
RowStyle	The style settings for the data rows in the DetailsView control. When the **AlternatingRowStyle** property is also set, the data rows are displayed alternating between the **RowStyle** settings and the **AlternatingRowStyle** settings.
FieldHeaderStyle	The style settings for the header column of the DetailsView control.

Events

The DetailsView control provides several events that you can program against. This allows you to run a custom routine whenever an event occurs. The following table lists the events supported by the DetailsView control. The DetailsView control also inherits these events from its base classes: DataBinding, DataBound, Disposed, Init, Load, PreRender, and Render.

EVENT	DESCRIPTION
ItemCommand	Occurs when a button is clicked in the DetailsView control.
ItemCreated	Occurs after all DetailsViewRow objects are created in the DetailsView control. This event is often used to modify the values of a record before it is displayed.
ItemDeleted	Occurs when a Delete button is clicked, but after the DetailsView control deletes the record from the data source. This event is often used to check the results of the delete operation.
ItemDeleting	Occurs when a Delete button is clicked, but before the DetailsView control deletes the record from the data source. This event is often used to cancel the delete operation.
ItemInserted	Occurs when an Insert button is clicked, but after the DetailsView control inserts the record. This event is often used to check the results of the insert operation.
ItemInserting	Occurs when an Insert button is clicked, but before the DetailsView control inserts the record. This event is often used to cancel the insert operation.
ItemUpdated	Occurs when an Update button is clicked, but after the DetailsView control updates the row. This event is often used to check the results of the update operation.
ItemUpdating	Occurs when an Update button is clicked, but before the DetailsView control updates the record. This event is often used to cancel the update operation.
ModeChanged	Occurs after the DetailsView control changes modes (edit, insert, or read-only mode). This event is often used to perform a task when the DetailsView control changes modes.

EVENT	DESCRIPTION
ModeChanging	Occurs before the DetailsView control changes modes (edit, insert, or read-only mode). This event is often used to cancel a mode change.
PageIndexChanged	Occurs when one of the pager buttons is clicked, but after the DetailsView control handles the paging operation. This event is commonly used when you need to perform a task after the user navigates to a different record in the control.
PageIndexChanging	Occurs when one of the pager buttons is clicked, but before the DetailsView control handles the paging operation. This event is often used to cancel the paging operation.

The Menu Control

The Menu control in ASP.NET 2.0 is designed to be a full-featured navigation system. It can be databound easily to hierarchical data sources such as the SiteMapDataSource.

A Menu controls structure can be defined declaratively or dynamically and consists of a single root node and any number of sub-nodes. The following code declaratively defines a menu for the Menu control.

```
<asp:menu id="NavigationMenu" disappearafter="2000" staticdisplaylevels="2" staticsubmenuindent="10"
orientation="Vertical" font-names="Arial" target="_blank" runat="server"> <staticmenuitemstyle
backcolor="LightSteelBlue" forecolor="Black"/> <statichoverstyle backcolor="LightSkyBlue"/>
<dynamicmenuitemstyle backcolor="Black" forecolor="Silver"/> <dynamichoverstyle backcolor="LightSkyBlue"
forecolor="Black"/> <items> <asp:menuitem navigateurl="Home.aspx" text="Home" tooltip="Home"> <asp:menuitem
navigateurl="Music.aspx" text="Music" tooltip="Music"> <asp:menuitem navigateurl="Classical.aspx"
text="Classical" tooltip="Classical"/> <asp:menuitem navigateurl="Rock.aspx" text="Rock" tooltip="Rock"/>
<asp:menuitem navigateurl="Jazz.aspx" text="Jazz" tooltip="Jazz"/> </asp:menuitem> <asp:menuitem
navigateurl="Movies.aspx" text="Movies" tooltip="Movies"> <asp:menuitem navigateurl="Action.aspx"
text="Action" tooltip="Action"/> <asp:menuitem navigateurl="Drama.aspx" text="Drama" tooltip="Drama"/>
<asp:menuitem navigateurl="Musical.aspx" text="Musical" tooltip="Musical"/> </asp:menuitem> </asp:menuitem>
</items> </asp:menu>
```

In the above example, the Home.aspx node is the root node. All other nodes are nested within the root node at various levels.

There are two types of menus that the Menu control can render; static menus and dynamic menus. Static menus consist of menu items that are always visible. Dynamic menus consist of menu items that are only visible when the user hovers over them with the mouse. Customers may often confuse static menus with menus defined declaratively and dynamic menus with menus that are databound at runtime. In fact, dynamic and static menus are unrelated to the method of population. The terms *static* and *dynamic* refer only to whether or not the menu is statically displayed by default or only displayed when the user takes some action.

The **StaticDisplayLevels** property is used to configure how many levels of the menu are static and therefore displayed by default. In the above example, setting the **StaticDisplayLevels** property to a value of 2 would cause the menu to statically display the Home node, the Music node, and the Movies node. All other nodes would be dynamically displayed when the user hovers over the parent node.

The **MaximumDynamicDisplayLevels** property configures the maximum number of dynamic levels the menu is capable of displaying. Any dynamic menus at a level higher than the value specified by the **MaximumDynamicDisplayLevels** property are discarded.

> **NOTE**
> It is almost certain that you might encounter situations where menus don't appear to render due to the MaximumDynamicDisplayLevels property. In those cases, ensure that the property is set sufficiently to allow for the display of the customers menus.

Data Binding the Menu Control

The Menu control can be bound to any hierarchical data source such as the SiteMapDataSource or the XMLDataSource. The SiteMapDataSource is the most commonly used method for data binding to a Menu control because it feeds off of the Web.sitemap file and its schema provides a known API to the Menu control. The listing below shows a simple Web.sitemap file.

```
<siteMap xmlns="http://schemas.microsoft.com/AspNet/SiteMap-File-1.0" > <siteMapNode url="~/default.aspx"
description="Our Home Page" title="Home"> <siteMapNode url="~/products/default.aspx" title="Products"
description="Our Products"> <siteMapNode url="~/products/winprods.aspx" title="Windows Products"
description="Windows Products" /> <siteMapNode url="~/products/webprods.aspx" title="Web Products"
description="Web Products" /> </siteMapNode> <siteMapNode url="~/services/default.aspx" title="Services"
description="Our Services"> <siteMapNode url="~/services/consulting.aspx" title="Consulting Services"
description="Consulting Services" /> <siteMapNode url="~/services/develop.aspx" title="Development Services"
description="Development Services" /> </siteMapNode> </siteMapNode> </siteMap>
```

Notice that there is only one root siteMapNode element, in this case, the Home element. Several attributes can be configured for each siteMapNode. The most commonly used attributes are:

- **url** Specifies the URL to display when a user clicks the menu item. If this attribute is not present, the node will simply post back when clicked.
- **title** Specifies the text that is displayed on the menu item.
- **description** Used as documentation for the node. Also displays as a tool tip when the mouse is hovered over the node.
- **siteMapFile** Allows for nested sitemaps. This attribute must point to a well-formed ASP.NET sitemap file.
- **roles** Allows for the appearance of a node to be controlled by ASP.NET security trimming.

Note that while these attributes are all optional, the behavior of the menu may not be what is expected if they are not specified. For example, if the *url* attribute is specified but the *description* attribute is not, the node will not be visible and there will be no way to navigate to the URL specified.

Controlling a Menus Operation

There are several properties that affect the operation of an ASP.NET Menu control; the **Orientation** property, the **DisappearAfter** property, the **StaticItemFormatString** property, and the **StaticPopoutImageUrl** property are just a few of these.

- The **Orientation** can be set to either *horizontal* or *vertical* and controls whether static menu items are laid out horizontally in a row or vertically and stacked upon one another. This property does not affect dynamic menus.
- The **DisappearAfter** property configures how long a dynamic menu should remain visible after the mouse has been moved away from it. The value is specified in milliseconds and defaults to 500. Setting this property to a value of -1 will cause the menu to never disappear automatically. In that case, the menu will only disappear when the user clicks outside of the menu.
- The **StaticItemFormatString** property makes it easy to maintain consistent verbiage in your menu system. When specifying this property, *{0}* should be entered in place of the description that appears in the data source. For example, in order to have the menu item from exercise 1 say Visit Our Products Page, etc., you would specify Visit Our {0} Page for the StaticItemFormatString. At runtime, ASP.NET will replace any occurrence of {0}

with the correct description for the menu item.

- The **StaticPopoutImageUrl** property specifies the image that is used to indicate that a particular menu node has child nodes that can be accessed by hovering over it. Dynamic menus will continue to use the default image.

Templated Menu Controls

The Menu control is a templated control and allows for two different ItemTemplates; the StaticItemTemplate and the DynamicItemTemplate. Using these templates, you can easily add server controls or user controls to your menus.

To edit the templates in Visual Studio .NET, click the Smart Tag button on the menu and either choose Edit Templates. You can then choose between editing the StaticItemTemplate or the DynamicItemTemplate.

Any controls added to the StaticItemTemplate will appear in the static menu when the page loads. Any controls added to the DynamicItemTemplate will appear on all pop-up menus.

Menu Events

The Menu control has two events that are unique to it; the **MenuItemClicked** and the **MenuItemDatabound** event.

The MenuItemClicked event is raised when a menu item is clicked. The MenuItemDatabound event is raised when a menu item is databound. The **MenuEventArgs** that is passed to the event handler provides access to the menu item via the Item property.

Controlling a Menus Appearance

You can also affect the appearance of a menu control using one or more of the many styles available to format menus. Among these are **StaticMenuStyle**, **DynamicMenuStyle**, **DynamicMenuItemStyle**, **DynamicSelectedStyle**, and **DynamicHoverStyle**. These properties are configured using a standard HTML Style string. For example, the following will affect the style for dynamic menus.

```
<DynamicMenuStyle BorderStyle="Outset" BorderWidth="1px"
    BackColor="#D6D3CE" />
```

> **NOTE**
> If you are using any of the Hover styles, you will need to add a <head> element in to the page with the *runat* element set to *server*.

Menu controls also support the use of ASP.NET 2.0 themes.

The TreeView Control

The TreeView control displays data in a tree-like structure. As with the Menu control, it can be easily data bound to any hierarchical data source such as the SiteMapDataSource.

The first question that customers are likely to ask about the TreeView control in ASP.NET 2.0 is whether or not it is related to the TreeView IE WebControl that was available for ASP.NET 1.x. It is not. The ASP.NET 2.0 TreeView control was written from the ground up and offers significant improvement over the IE TreeView WebControl that was previously available.

I won't go into detail on how to bind a TreeView control to a site map as it is performed in exactly the same way as

the Menu control. However, the TreeView control has some distinct differences in the way that it operates.

By default, a TreeView control appears fully expanded. To change the level of expansion upon initial load, modify the **ExpandDepth** property of the control. This is particularly important in cases where the TreeView is databound upon expanding particular nodes.

DataBinding the TreeView Control

Unlike the Menu control, the TreeView lends itself well to handling large amounts of data. Therefore, in addition to databinding to a SiteMapDataSource or XMLDataSource, the TreeView is often data bound to a DataSet or other relational data. In cases where the TreeView control is bound to large amounts of data, it is best to bind only to data that is actually visible in the control. You can then data bind to additional data as TreeView nodes are expanded.

In these cases, the **PopulateOnDemand** property of the TreeView should be set to *true*. You will then need to provide an implementation for the **TreeNodePopulate** method.

Data Binding Without PostBack

Notice that when you expand a node in the previous example for the first time, the page posts back and refreshes. Thats not a problem in this example, but you can imagine that it might be in a production environment with a large amount of data. A better scenario would be one in which the TreeView would still dynamically populate its nodes, but without a post back to the server.

By setting the **PopulateNodesFromClient** and the **PopulateOnDemand** properties to true, the ASP.NET TreeView control will dynamically populate nodes without a post back. When the parent node is expanded, an XMLHttp request is made from the client and the OnTreeNodePopulate event is fired. The server responds with an XML data island which is then used to data bind the child nodes.

ASP.NET dynamically creates the client code that implements this functionality. The <script> tags that contain the script are generated pointing to an AXD file. For example, the listing below shows the script links for the script code that generates the XMLHttp request.

```
<script src="/WebSite1/WebResource.axd?d=QQG9vSdBi4_k2y9AeP_iww2&
    amp;t=632514255396426531"
    type="text/javascript"></script>
```

If you browse the AXD file above in your browser and open it, you will see the code that implements the XMLHttp request. This method prevents customers from modifying the script file.

Controlling the Operation of the TreeView Control

The TreeView control has several properties that affect the operation of the control. The most obvious properties are the **ShowCheckBoxes**, **ShowExpandCollapse**, and **ShowLines**.

The **ShowCheckBoxes** property affects whether or not nodes display a check box when rendered. The valid values for this property are **None**, **Root**, **Parent**, **Leaf**, and **All**. These affect the TreeView control as follows:

PROPERTY VALUE	EFFECT
None	Checkboxes are not displayed on any nodes. This is the default setting.
Root	A checkbox is only displayed on the root node.

PROPERTY VALUE	EFFECT
Parent	A checkbox is only displayed on those nodes that have child nodes. Those child nodes can be parent nodes or leaf nodes.
Leaf	A checkbox is displayed only on those nodes that have no child nodes.
All	A checkbox is displayed on all nodes.

When checkboxes are being used, the **CheckedNodes** property will return a collection of TreeView nodes that are checked upon postback.

The **ShowExpandCollapse** property controls the appearance of the expand/collapse image next to root and parent nodes. If this property is set to **false**, TreeView nodes are rendered as hyperlinks and are expanded/collapsed by clicking on the link.

The **ShowLines** property controls whether or not lines are displayed connecting parent nodes to child nodes. When **false** (the default), no lines are displayed. When **true**, the TreeView control will use lines images in the folder specified by the **LineImagesFolder** property.

To customize the appearance of TreeView lines, Visual Studio .NET 2005 includes a Line Designer tool. You can access this tool using the Smart Tag button on the TreeView control as below.

Figure 1

When select the **Customize Line Images** menu option, the Line Designer tool will be launched allowing you to configure the appearance of TreeView lines.

TreeView Events

The TreeView control has the following unique events:

- SelectedNodeChanged Occurs when a node is selected based upon the **SelectAction** property.
- TreeNodeCheckChanged Occurs when a nodes checkboxs state is changed.
- TreeNodeExpanded Occurs when a node is expanded based upon the **SelectAction** property.
- TreeNodeCollapsed Occurs when a node is collapsed.
- TreeNodeDataBound Occurs when a node is data bound.
- TreeNodePopulate Occurs when a node is populated.

The **SelectAction** property allows you to configure which event is fired when a node is selected. The SelectAction property provides the following actions:

- TreeNodeSelectAction.Expand Raises TreeNodeExpanded when the node is selected.
- TreeNodeSelectAction.None Raises no event when the node is selected.
- TreeNodeSelectAction.Select Raises the SelectedNodeChanged event when the node is selected.

- TreeNodeSelectAction.SelectExpand Raises both the SelectedNodeChanged event and the TreeNodeExpanded event when the node is selected.

Controlling Appearance with Styles

The TreeView control provides many properties for controlling the appearance of the control with styles. The following properties are available.

PROPERTY NAME	CONTROLS
HoverNodeStyle	Controls the style of nodes when the mouse is hovered over them.
LeafNodeStyle	Controls the style of leaf nodes.
NodeStyle	Controls the style for all nodes. Specific node styles (such as LeafNodeStyle) override this style.
ParentNodeStyle	Controls the style for all parent nodes.
RootNodeStyle	Controls the style for the root node.
SelectedNodeStyle	Controls the style for the selected node.

Each of these properties is read-only. However, they will each return a **TreeNodeStyle** object, and the properties of that object can be modified using the *property-subproperty* format. For example, to set the **ForeColor** property of the **SelectedNodeStyle**, you would use the following syntax:

```
<asp:TreeView id=sampleTreeView
    SelectedNodeStyle-ForeColor=Blue
    runat=server>
```

Notice that the tag above is not closed. That is because when using the declarative syntax shown here, you would include the TreeViews nodes in the HTML code as well.

The style properties can also be specified in code using the *property.subproperty* format. For example, to set the **ForeColor** property of the **RootNodeStyle** in code, you would use the following syntax:

```
treeView1.RootNodeStyle.ForeColor = System.Drawing.Color.Red;
```

> **NOTE**
> For a comprehensive list of the different style properties, see the MSDN documentation on the TreeNodeStyle object.

The SiteMapPath Control

The SiteMapPath control provides a bread crumb navigation control for ASP.NET developers. Like the other navigation controls, it can be easily data bound to hierarchical data sources such as the SiteMapDataSource or XmlDataSource.

A SiteMapPath control is made up of SiteMapNodeItem objects. There are three types of nodes; the Root node, Parent nodes, and the Current node. The root node is the node at the top of the hierarchical structure. The current node represents the current page. All other nodes are parent nodes.

Controlling the Operation of the SiteMapPath Control

The properties that control the operation of the SiteMapPath control are as follows:

PROPERTY	DESCRIPTION OF PROPERTY
ParentLevelsDisplayed	Controls how many parent nodes are displayed. The default is -1 which imposes no restriction on the number of parent nodes displayed.
PathDirection	Controls the direction of the SiteMapPath. Valid values are RootToCurrent (default) and CurrentToRoot.
PathSeparator	A String that controls the character that separates nodes in a SiteMapPath control. The default value is :.
RenderCurrentNodeAsLink	A Boolean value that controls whether or not the current node is rendered as a link. The default is False.
SkipLinkText	Assists with accessibility when the page is viewed by screen readers. This property allows screen readers to skip the SiteMapPath control. To disable this feature, set the property to String.Empty.

Templated SiteMapPath Controls

The SiteMapControl is a templated control, and as such, you can define different templates for use in displaying the control. To edit templates in a SiteMapPath control, click the Smart Tag button on the control and choose Edit Templates from the menu. This displays the SiteMapTasks menu as shown below where you can choose between the different templates available.

Figure 2

The **NodeTemplate** template refers to any node in the SiteMapPath. If the node is a root node or the current node and a **RootNodeTemplate** or **CurrentNodeTemplate** is configured, the NodeTemplate is overridden.

SiteMapPath Events

The SiteMapPath control has two events that are not derived from the Control class; the **ItemCreated** event and the **ItemDataBound** event. The ItemCreated event is raised when a SiteMapPath item is created. ItemDataBound is raised when the DataBind method is called during the data binding of a SiteMapPath node. A **SiteMapNodeItemEventArgs** object provides access to the specific SiteMapNodeItem via the Item property.

Controlling Appearance with Styles

The following styles are available for formatting of a SiteMapPath control.

PROPERTY NAME	CONTROLS
CurrentNodeStyle	Controls the style of the text for the current node.
RootNodeStyle	Controls the style of the text for the root node.
NodeStyle	Controls the style of the text for all nodes assuming that a CurrentNodeStyle or RootNodeStyle doesnt apply.

The NodeStyle property is overridden by either the CurrentNodeStyle or the RootNodeStyle. Each of these properties is read-only and returns a **Style** object. To affect the appearance of a node using one of these properties, you will need to set the properties of the Style object that is returned. For example, the code below changes the forecolor property of the current node.

```
<asp:SiteMapPath runat="server" ID="SiteMapPath1"
  CurrentNodeStyle-ForeColor="Orange"/>
```

The property can also be applied programmatically as follows:

```
this.SiteMapPath1.CurrentNodeStyle.ForeColor =
    System.Drawing.Color.Orange;
```

NOTE

If a template is applied, the style will not be applied.

Lab 1: Configuring an ASP.NET Menu Control

1. Create a new Web site.
2. Add a Site Map file by selecting File, New, File and choosing Site Map from the list of file templates.
3. Open the site map (Web.sitemap by default) and modify it so that it looks like the listing below. The pages to which you are linking in the site map file do not really exist, but that will not be an issue for this exercise.

```
<?xml version="1.0" encoding="utf-8" ?>
<siteMap xmlns="http://schemas.microsoft.com/AspNet/SiteMap-File-1.0" >
    <siteMapNode url="~/default.aspx">
        <siteMapNode url="~/products/default.aspx"
          title="Products" description="Our Products">
            <siteMapNode url="~/products/winprods.aspx"
              title="Windows Products" description="Windows Products" />
            <siteMapNode url="~/products/webprods.aspx"
              title="Web Products" description="Web Products" />
        </siteMapNode>
        <siteMapNode url="~/services/default.aspx"
          title="Services" description="Our Services">
            <siteMapNode url="~/services/consulting.aspx"
              title="Consulting Services"
              description="Consulting Services" />
            <siteMapNode url="~/services/develop.aspx"
              title="Development Services"
              description="Development Services" />
        </siteMapNode>
    </siteMapNode>
</siteMap>
```

4. Open the default Web form in Design view.
5. From the Navigation section of the Toolbox, add a new Menu control to the page.
6. From the Data section of the Toolbox, add a new SiteMapDataSource. The SiteMapDataSource will automatically use the Web.sitemap file in your site. (The Web.sitemap file *must* be in the root folder of the site.)
7. Click the Menu control and then click the Smart Tag button to display the Menu Tasks dialog.
8. In the Choose Data Source dropdown, select SiteMapDataSource1.
9. Click the AutoFormat link and choose a format for the Menu.
10. In the Properties pane, set the **StaticDisplayLevels** property to 2. The Menu control should now display the Home, Products, and Services node in the Designer.
11. Browse the page in your browser to use the menu. (Because the pages you ve added to the site map don't actually exist, you will see an error when you try and browse to them.)

Experiment with changing the StaticDisplayLevels and the MaximumDynamicDisplayLevels properties and see how they affect how the menu is rendered.

Lab 2: Dynamically Binding a TreeView Control

This exercise assumes that you have SQL Server running locally and that the Northwind database is present on the SQL Server instance. If these conditions are not met, please change the connection string in the sample. Note that you may also need to specify SQL Server authentication instead of a trusted connection.

1. Create a new Web site.
2. Switch to Code view for Default.aspx and replace all code with the code listed below.

```
<%@ Page Language="C#" %>
<%@ Import Namespace="System.Data" %>
<%@ Import Namespace="System.Data.SqlClient" %>

<script runat="server">
    void PopulateNode(Object sender, TreeNodeEventArgs e) {
        // Call the appropriate method to populate a node at a particular level.
        switch (e.Node.Depth) {
            case 0:
                // Populate the first-level nodes.
                PopulateCategories(e.Node);
                break;
            case 1:
                // Populate the second-level nodes.
                PopulateProducts(e.Node);
                break;
            default:
                // Do nothing.
                break;
        }

    }
    void PopulateCategories(TreeNode node) {

        // Query for the product categories. These are the values
        // for the second-level nodes.
        DataSet ResultSet = RunQuery("Select CategoryID, CategoryName From Categories");
        // Create the second-level nodes.
        if (ResultSet.Tables.Count > 0) {

            // Iterate through and create a new node for each row in the query results.
```

```
            // Notice that the query results are stored in the table of the DataSet.
            foreach (DataRow row in ResultSet.Tables[0].Rows) {

                // Create the new node. Notice that the CategoryId is stored in the Value property
                // of the node. This will make querying for items in a specific category easier when
                // the third-level nodes are created.
                TreeNode newNode = new TreeNode();
                newNode.Text = row["CategoryName"].ToString();
                newNode.Value = row["CategoryID"].ToString();
                // Set the PopulateOnDemand property to true so that the child nodes can be
                // dynamically populated.
                newNode.PopulateOnDemand = true;

                // Set additional properties for the node.
                newNode.SelectAction = TreeNodeSelectAction.Expand;

                // Add the new node to the ChildNodes collection of the parent node.
                node.ChildNodes.Add(newNode);

            }

        }

    }
    void PopulateProducts(TreeNode node) {
        // Query for the products of the current category. These are the values
        // for the third-level nodes.
        DataSet ResultSet = RunQuery("Select ProductName From Products Where CategoryID=" +
node.Value);
        // Create the third-level nodes.
        if (ResultSet.Tables.Count > 0) {

            // Iterate through and create a new node for each row in the query results.
            // Notice that the query results are stored in the table of the DataSet.
            foreach (DataRow row in ResultSet.Tables[0].Rows) {

                // Create the new node.
                TreeNode NewNode = new TreeNode(row["ProductName"].ToString());

                // Set the PopulateOnDemand property to false, because these are leaf nodes and
                // do not need to be populated.
                NewNode.PopulateOnDemand = false;

                // Set additional properties for the node.
                NewNode.SelectAction = TreeNodeSelectAction.None;

                // Add the new node to the ChildNodes collection of the parent node.
                node.ChildNodes.Add(NewNode);

            }

        }
    }
    DataSet RunQuery(String QueryString) {
        // Declare the connection string. This example uses Microsoft SQL Server
        // and connects to the Northwind sample database.
        String ConnectionString = "server=localhost;database=NorthWind;Integrated Security=SSPI";
        SqlConnection DBConnection = new SqlConnection(ConnectionString);
        SqlDataAdapter DBAdapter;
        DataSet ResultsDataSet = new DataSet();
        try {
            // Run the query and create a DataSet.
            DBAdapter = new SqlDataAdapter(QueryString, DBConnection);
            DBAdapter.Fill(ResultsDataSet);
            // Close the database connection.
            DBConnection.Close();
        } catch (Exception ex) {
            // Close the database connection if it is still open.
            if (DBConnection.State == ConnectionState.Open) {
```

```
                DBConnection.Close();
            }

            Message.Text = "Unable to connect to the database.";
        }
        return ResultsDataSet;
    }
</script>

<html>
<body>
    <form id="Form1" runat="server">
        <h3>
            TreeView PopulateNodesFromClient Example</h3>
        <asp:TreeView ID="LinksTreeView"
          Font-Name="Arial" ForeColor="Blue" EnableClientScript="true"
          PopulateNodesFromClient="false"
          OnTreeNodePopulate="PopulateNode" runat="server"
            ExpandDepth="0">
            <Nodes>
                <asp:TreeNode Text="Inventory" SelectAction="Expand"
                              PopulateOnDemand="True" Value="Inventory" />
            </Nodes>
        </asp:TreeView>
        <br>
        <br>
        <asp:Label ID="Message" runat="server" />
    </form>
</body>
</html>
```

3. Save the page as treeview.aspx.
4. Browse the page.
5. When the page is first displayed, view the source of the page in your browser. Note that only the visible nodes were sent to the client.
6. Click the plus sign next to any node.
7. View source on the page again. Notice that the newly displayed nodes are now present.

Lab 3: Details View and Editing Data Using a GridView and DetailsView

1. Create a new Web site.
2. Add a new web.config to the Web site.
3. Add a connection string to the web.config file as shown below:

```
<connectionStrings>
    <add name="Northwind"
         providerName="System.Data.SqlClient"
         connectionString="Data Source=localhost;Integrated Security=SSPI;
         Initial Catalog=Northwind;"/>
</connectionStrings>
```

> **NOTE**
>
> You may need to change the connection string based upon your environment.

4. Save and close the web.config file.

5. Open Default.aspx and add a new SqlDataSource control.
6. Change the ID of the SqlDataSource control to **Products**.
7. In the **SqlDataSource Tasks** menu, click **Configure Data Source**.
8. Select **Northwind** in the connection dropdown and click Next.
9. Select **Products** from the **Name** dropdown and check the **ProductID**, **ProductName**, **UnitPrice**, and **UnitsInStock** checkboxes as shown below.

```
**Figure 3**
```

10. Click **Next**.
11. Click **Finish**.
12. Switch to Source view and examine the code that was generated. Notice the **SelectCommand**, **DeleteCommand**, **InsertCommand**, and **UpdateCommand** that were added to the SqlDataSource control. Also notice the parameters that were added.
13. Switch to Design view and add a new GridView control to the page.
14. Select **Products** from the **Choose Data Source** dropdown.
15. Check **Enable Paging** and **Enable Selection** as shown below.

```
**Figure 4**
```

16. Click the **Edit Columns** link and make sure that **Auto-generate fields** is checked.
17. Click **OK**.
18. With the GridView control selected, click the button next to the **DataKeyNames** property in the Properties pane.
19. Select **ProductID** from the **Available data fields** list and click the > button to add it.
20. Click OK.
21. Add a new SqlDataSource control to the page.
22. Change the ID of the SqlDataSource control to **Details**.
23. From the SqlDataSource Tasks menu, choose **Configure Data Source**.
24. Choose **Northwind** from the dropdown and click **Next**.
25. Select **Products** from the **Name** dropdown and check the *** checkbox in the Columns listbox.**
26. Click the **WHERE** button.
27. Select **ProductID** from the **Column** dropdown.
28. Select = in the Operator dropdown.
29. Select **Control** from the **Source** dropdown.
30. Select **GridView1** from the **Control ID** dropdown.
31. Click the **Add** button to add the WHERE clause.
32. Click **OK**.
33. Click the **Advanced** button and check the **Generate INSERT, UPDATE, and DELETE statements** checkbox.
34. Click **OK**.
35. Click **Next** and click **Finish**.
36. Add a DetailsView control to the page.
37. In the **Choose Data Source** dropdown, choose **Details**.
38. Check the **Enable Editing** checkbox as shown below.

```
**Figure 5**
```

39. Save the page and browse Default.aspx.
40. Click the **Select** link next to different records to see the DetailsView update automatically.
41. Click the **Edit** link in the DetailsView control.
42. Make a change to the record and click **Update**.

Caching

4/10/2020 • 18 minutes to read • Edit Online

by Microsoft

> An understanding of caching is important for a well-performing ASP.NET application. ASP.NET 1.x offered three different options for caching; output caching, fragment caching, and the cache API.

An understanding of caching is important for a well-performing ASP.NET application. ASP.NET 1.x offered three different options for caching; output caching, fragment caching, and the cache API. ASP.NET 2.0 offers all three of these methods, but it adds some significant additional features. There are several new cache dependencies and developers now have the option to create custom cache dependencies as well. The configuration of caching has also been improved significantly in ASP.NET 2.0.

New Features

Cache Profiles

Cache profiles allow developers to define specific cache settings that can then be applied to individual pages. For example, if you have some pages that should be expired from cache after 12 hours, you can easily create a cache profile that can be applied to those pages. To add a new cache profile, use the <outputCacheSettings> section in the configuration file. For example, below is the configuration of a cache profile called *twoday* that configures a cache duration of 12 hours.

```
<outputCacheSettings>
    <outputCacheProfiles>
        <add name="TwoDay" duration="43200" />
    </outputCacheProfiles>
</outputCacheSettings>
```

To apply this cache profile to a particular page, use the CacheProfile attribute of the @ OutputCache directive as shown below:

```
<%@ OutputCache CacheProfile="TwoDay" %>
```

Custom Cache Dependencies

ASP.NET 1.x developers cried out for custom cache dependencies. In ASP.NET 1.x, the CacheDependency class was sealed which prevented developers from deriving their own classes from it. In ASP.NET 2.0, that limitation is removed and developers are free to develop their own custom cache dependencies. The CacheDependency class allows for the creation of a custom cache dependency based on files, directories, or cache keys.

For example, the code below creates a new custom cache dependency based on a file called stuff.xml located in the root of the Web application:

```
System.Web.Caching.CacheDependency dep = new
    System.Web.Caching.CacheDependency(Server.MapPath("stuff.xml"));
Response.AddCacheDependency(dep);
Cache.Insert("key", "value");
```

In this scenario, when the stuff.xml file changes, the cached item is invalidated.

It is also possible to create a custom cache dependency using cache keys. Using this method, the removal of the cache key will invalidate the cached data. The following example illustrates this:

```
// insert a value into cache that will serve
// as the cache key
Cache["CacheKey"] = "something";

// create an array of cache keys
string[] keys = new String[1];
keys[0] = "CacheKey";

CacheDependency dep = new CacheDependency(null, keys);

// insert an item into cache with a dependency on
// the above CacheDependency
Cache.Insert("Key", "Value", dep);
```

To invalidate the item that was inserted above, simply remove the item that was inserted into cache to act as the cache key.

```
// Remove the cache item that serves as the cache key
Cache.Remove("CacheKey");
```

Note that the key of the item that acts as the cache key must be the same as the value added to the array of cache keys.

Polling-Based SQL Cache Dependencies(Also called Table-Based Dependencies)

SQL Server 7 and 2000 use the polling-based model for SQL cache dependencies. The polling-based model uses a trigger on a database table that is triggered when data in the table change. That trigger updates a **changeId** field in the notification table that ASP.NET checks periodically. If the **changeId** field has been updated, ASP.NET knows that the data have changed and it invalidates the cached data.

> **NOTE**
>
> SQL Server 2005 can also use the polling-based model, but because the polling-based model is not the most efficient model, it is advisable to use a query-based model (discussed later) with SQL Server 2005.

In order for a SQL cache dependency using the polling-based model to work correctly, the tables must have notifications enabled. This can be accomplished programmatically using the SqlCacheDependencyAdmin class or by using the aspnet_regsql.exe utility.

The following command line registers the Products table in the Northwind database located on a SQL Server instance named *dbase* for SQL cache dependency.

```
aspnet_regsql -S dbase -ed -d Northwind -E -et -t Products
```

The following is an explanation of the command line switches used in the above command:

COMMAND LINE SWITCH	PURPOSE
-S *server*	Specifies the server name.
-ed	Specifies that the database should be enabled for SQL cache dependency.
-d *database_name*	Specifies the database name that should be enabled for SQL cache dependency.
-E	Specifies that aspnet_regsql should use Windows authentication when connecting to the database.
-et	Specifies that we are enabling a database table for SQL cache dependency.
-t *table_name*	Specifies the name of the database table to enable for SQL cache dependency.

> **NOTE**
> There are other switches available for aspnet_regsql.exe. For a complete list, run aspnet_regsql.exe -? from a command line.

When this command runs the following changes are made to the SQL Server database:

- An **AspNet_SqlCacheTablesForChangeNotification** table is added. This table contains one row for each table in the database for which a SQL cache dependency has been enabled.
- The following stored procedures are created inside of the database:

ASPNET_SQLCACHEPOLLINGSTOREDPROCEDURE	QUERIES THE ASPNET_SQLCACHETABLESFORCHANGENOTIFICATION TABLE AND RETURNS ALL TABLES THAT ARE ENABLED FOR SQL CACHE DEPENDENCY AND THE VALUE OF CHANGEID FOR EACH TABLE. THIS STORED PROC IS USED FOR POLLING TO DETERMINE IF DATA HAVE CHANGED.
AspNet_SqlCacheQueryRegisteredTablesStoredProcedure	Returns all of the tables enabled for SQL cache dependency by querying the AspNet_SqlCacheTablesForChangeNotification table and returns all tables enabled for SQL cache dependency.
AspNet_SqlCacheRegisterTableStoredProcedure	Registers a table for SQL cache dependency by adding the necessary entry in the notification table and adds the trigger.
AspNet_SqlCacheUnRegisterTableStoredProcedure	Unregisters a table for SQL cache dependency by removing the entry in the notification table and removes the trigger.
AspNet_SqlCacheUpdateChangeIdStoredProcedure	Updates the notification table by incrementing the changeId for the changed table. ASP.NET uses this value to determine if the data have changed. As indicated below, this stored proc is executed by the trigger created when the table is enabled.

- A SQL Server trigger called ***table_name*_AspNet_SqlCacheNotification_Trigger** is created for the table. This trigger executes the AspNet_SqlCacheUpdateChangeIdStoredProcedure when an INSERT, UPDATE, or DELETE is performed on the table.

- A SQL Server role called **aspnet_ChangeNotification_ReceiveNotificationsOnlyAccess** is added to the database.

The **aspnet_ChangeNotification_ReceiveNotificationsOnlyAccess** SQL Server role has EXEC permissions to the AspNet_SqlCachePollingStoredProcedure. In order for the polling model to work correctly, you must add your process account to the aspnet_ChangeNotification_ReceiveNotificationsOnlyAccess role. The aspnet_regsql.exe tool will not do this for you.

Configuring Polling-Based SQL Cache Dependencies

There are several steps that are required for configuring polling-based SQL cache dependencies. The first step is to enable the database and the table as discussed above. Once that step is complete, the rest of the configuration is as follows:

- Configuring the ASP.NET configuration file.
- Configuring the SqlCacheDependency

Configuring the ASP.NET Configuration File

In addition to adding a connection string as discussed in a previous module, you must also configure a <cache> element with a <sqlCacheDependency> element as shown below:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <connectionStrings>
    <add name="Pubs"
    connectionString="Data Source=(local);
      Initial Catalog=pubs;Integrated Security=true;"
    providerName="System.Data.SqlClient" />
  </connectionStrings>
  <system.web>
    <caching>
      <sqlCacheDependency enabled = "true" pollTime = "60000" >
        <databases>
          <add name="pubs" connectionStringName = "pubs" pollTime = "9000000" />
        </databases>
      </sqlCacheDependency>
    </caching>
  </system.web>
</configuration>
```

This configuration enables a SQL cache dependency on the *pubs* database. Note that the pollTime attribute in the <sqlCacheDependency> element defaults to 60000 milliseconds or 1 minute. (This value cannot be less than 500 milliseconds.) In this example, the <add> element adds a new database and overrides the pollTime, setting it to 9000000 milliseconds.

Configuring the SqlCacheDependency

The next step is to configure the SqlCacheDependency. The easiest way to accomplish that is to specify the value for the SqlDependency attribute in the @ Outcache directive as follows:

```
<%@ OutputCache duration="60"
    VaryByParam="none" SqlDependency="pubs:authors" %>
```

In the above @ OutputCache directive, a SQL cache dependency is configured for the *authors* table in the *pubs* database. Multiple dependencies can be configured by separating them with a semi-colon like so:

```
<%@ OutputCache duration="60"
    VaryByParam="none"
    SqlDependency="database_name:table_name;database_name:table_name" %>
```

Another method of configuring the SqlCacheDependency is to do so programmatically. The following code creates a new SQL cache dependency on the *authors* table in the *pubs* database.

```
SqlCacheDependency dep = new SqlCacheDependency("pubs", "authors");
```

One of the benefits of programmatically defining the SQL cache dependency is that you can handle any exceptions that might occur. For example, if you attempt to define a SQL cache dependency for a database that has not been enabled for notification, a **DatabaseNotEnabledForNotificationException** exception will be thrown. In that case, you can attempt to enable the database for notifications by calling the **SqlCacheDependencyAdmin.EnableNotifications** method and passing it the database name.

Likewise, if you attempt to define a SQL cache dependency for a table that has not been enabled for notification, a **TableNotEnabledForNotificationException** will be thrown. You can then call the **SqlCacheDependencyAdmin.EnableTableForNotifications** method passing it the database name and table name.

The following code sample illustrates how to properly configure exception handling when configuring a SQL cache dependency.

```
try {
    SqlCacheDependency SqlDep = new
    SqlCacheDependency("pubs", "authors");
} catch (DatabaseNotEnabledForNotificationException exDBDis) {
    try {
        SqlCacheDependencyAdmin.EnableNotifications("pubs");
    } catch (UnauthorizedAccessException exPerm) {
        Response.Redirect("ErrorPage.htm");
    }
} catch (TableNotEnabledForNotificationException exTabDis) {
    try {
        SqlCacheDependencyAdmin.EnableTableForNotifications("pubs",
        "authors");
    } catch (System.Data.SqlClient.SqlException exc) {
        Response.Redirect("ErrorPage.htm");
    }
} finally {
    Cache.Insert("SqlSource", Source1, SqlDep);
}
```

Query-Based SQL Cache Dependencies (SQL Server 2005 Only)

When using SQL Server 2005 for SQL cache dependency, the polling-based model is not necessary. When used with SQL Server 2005, SQL cache dependencies communicate directly via SQL connections to the SQL Server instance (no further configuration is necessary) using SQL Server 2005 query notifications.

The simplest way to enable query-based notification is to do so declaratively by setting the **SqlCacheDependency** attribute of the data source object to **CommandNotification** and setting the **EnableCaching** attribute to **true**. Using this method, no code is required. If the result of a command executed against the data source changes, it will invalidate the cache data.

The following example configures a data source control for SQL cache dependency:

```
<asp:SqlDataSource ID="ProductList" runat="server"
    ConnectionString="<%$ ConnectionStrings:Northwind %>"
    EnableCaching="true"
    SqlCacheDependency="CommandNotification"
    SelectCommand="SELECT * FROM [Products]" />
```

In this case, if the query specified in the **SelectCommand** returns a different result than it did originally, the results that are cached are invalidated.

You can also specify that all of your data sources be enabled for SQL cache dependencies by setting the **SqlDependency** attribute of the **@ OutputCache** directive to **CommandNotification**. The example below illustrates this.

```
<%@ OutputCache SqlDependency="CommandNotification"
    duration="60" VaryByParam="none" %>
```

> **NOTE**
>
> For more information on query notifications in SQL Server 2005, see the SQL Server Books Online.

Another method of configuring a query-based SQL cache dependency is to do so programmatically using the SqlCacheDependency class. The following code sample illustrates how this is accomplished.

```
string sql = "SELECT ProductName, ProductID FROM Products";
SqlConnection conn = new
SqlConnection(ConfigurationManager.ConnectionStrings["Northwind"].ConnectionString);
SqlCommand cmd = new SqlCommand(sql, conn);
SqlCacheDependency dep = new SqlCacheDependency(cmd);
Response.AddCacheDependency(dep);
```

Post-Cache Substitution

Caching a page can dramatically increase the performance of a Web application. However, in some cases you need most of the page to be cached and some fragments within the page to be dynamic. For example, if you create a page of news stories that is entirely static for set periods of time, you can set the entire page to be cached. If you wanted to include a rotating ad banner that changed on every page request, then the part of the page containing the advertisement needs to be dynamic. To allow you to cache a page but substitute some content dynamically, you can use ASP.NET post-cache substitution. With post-cache substitution, the entire page is output cached with specific parts marked as exempt from caching. In the example of the ad banners, the AdRotator control allows you to take advantage of post-cache substitution so that ads dynamically created for each user and for each page refresh.

There are three ways to implement post-cache substitution:

- Declaratively, using the Substitution control.
- Programmatically, using the Substitution control API.
- Implicitly, using the AdRotator control.

Substitution Control

The ASP.NET Substitution control specifies a section of a cached page that is created dynamically rather than cached. You place a Substitution control at the location on the page where you want the dynamic content to

appear. At run time, the Substitution control calls a method that you specify with the MethodName property. The method must return a string, which then replaces the content of the Substitution control. The method must be a static method on the containing Page or UserControl control. Using the substitution control causes client-side cacheability to be changed to server cacheability, so that the page will not be cached on the client. This ensures that future requests to the page call the method again to generate dynamic content.

Substitution API

To create dynamic content for a cached page programmatically, you can call the WriteSubstitution method in your page code, passing it the name of a method as a parameter. The method that handles the creation of the dynamic content takes a single HttpContext parameter and returns a string. The return string is the content that will be substituted at the given location. An advantage of calling the WriteSubstitution method instead of using the Substitution control declaratively is that you can call a method of any arbitrary object rather than calling a static method of the Page or the UserControl object.

Calling the WriteSubstitution method causes client-side cacheability to be changed to server cacheability, so that the page will not be cached on the client. This ensures that future requests to the page call the method again to generate dynamic content.

AdRotator Control

The AdRotator server control implements support for post-cache substitution internally. If you place an AdRotator control on your page, it will render unique advertisements on each request, regardless of whether the parent page is cached. As a result, a page that includes an AdRotator control is only cached server-side.

ControlCachePolicy Class

The ControlCachePolicy class allows for the programmatic control of fragment caching using user controls. ASP.NET embeds user controls within a BasePartialCachingControl instance. The BasePartialCachingControl class represents a user control that has output caching enabled.

When you access the BasePartialCachingControl.CachePolicy property of a PartialCachingControl control, you will always receive a valid ControlCachePolicy object. However, if you access the UserControl.CachePolicy property of a UserControl control, you receive a valid ControlCachePolicy object only if the user control is already wrapped by a BasePartialCachingControl control. If it is not wrapped, the ControlCachePolicy object returned by the property will throw exceptions when you attempt to manipulate it because it does not have an associated BasePartialCachingControl. To determine whether a UserControl instance supports caching without generating exceptions, inspect the SupportsCaching property.

Using the ControlCachePolicy class is one of several ways you can enable output caching. The following list describes methods you can use to enable output caching:

- Use the @ OutputCache directive to enable output caching in declarative scenarios.
- Use the PartialCachingAttribute attribute to enable caching for a user control in a code-behind file.
- Use the ControlCachePolicy class to specify cache settings in programmatic scenarios in which you are working with BasePartialCachingControl instances that have been cache-enabled using one of the previous methods and dynamically loaded using the System.Web.UI.TemplateControl.LoadControl method.

A ControlCachePolicy instance can be successfully manipulated only between the Init and PreRender stages of the control life cycle. If you modify a ControlCachePolicy object after the PreRender phase, ASP.NET throws an exception because any changes made after the control is rendered cannot actually affect cache settings (a control is cached during the Render stage). Finally, a user control instance (and therefore its ControlCachePolicy object) is only available for programmatic manipulation when it is actually rendered.

Changes to Caching Configuration - The <caching> Element

There are several changes to caching configuration in ASP.NET 2.0. The <caching> element is new in ASP.NET 2.0

and allows you to make caching configuration changes in the configuration file. The following attributes are available.

ELEMENT	DESCRIPTION
cache	Optional element. Defines global application cache settings.
outputCache	Optional element. Specifies application-wide output-cache settings.
outputCacheSettings	Optional element. Specifies output-cache settings that can be applied to pages in the application.
sqlCacheDependency	Optional element. Configures the SQL cache dependencies for an ASP.NET application.

The <cache> Element

The following attributes are available in the <cache> element:

ATTRIBUTE	DESCRIPTION
disableMemoryCollection	Optional **Boolean** attribute. Gets or sets a value indicating whether the cache memory collection that occurs when the machine is under memory pressure is disabled.
disableExpiration	Optional **Boolean** attribute. Gets or sets a value indicating whether cache expiration is disabled. When disabled, cached items do not expire and background scavenging of expired cache items does not occur.
privateBytesLimit	Optional **Int64** attribute. Gets or sets a value indicating the maximum size of an application's private bytes before the cache starts flushing expired items and attempting to reclaim memory. This limit includes both memory used by the cache as well as normal memory overhead from the running application. A setting of zero indicates that ASP.NET will use its own heuristics for determining when to start reclaiming memory.
percentagePhysicalMemoryUsedLimit	Optional **Int32** attribute. Gets or sets a value indicating the maximum percentage of a machine's physical memory that can be consumed by an application before the cache starts flushing expired items and attempting to reclaim memory This memory usage includes both memory used by the cache as well as the normal memory usage of the running application. A setting of zero indicates that ASP.NET will use its own heuristics for determining when to start reclaiming memory.
privateBytesPollTime	Optional **TimeSpan** attribute. Gets or sets a value indicating the time interval between polling for the application's private bytes memory usage.

The <outputCache> Element

The following attributes are available for the <outputCache> element.

ATTRIBUTE	DESCRIPTION
enableOutputCache	Optional **Boolean** attribute. Enables/disables the page output cache. If disabled, no pages are cached regardless of the programmatic or declarative settings. Default value is **true**.
enableFragmentCache	Optional **Boolean** attribute. Enables/disables the application fragment cache. If disabled, no pages are cached regardless of the @ OutputCache directive or caching profile used. Includes a cache-control header indicating that upstream proxy servers as well as browser clients should not attempt to cache page output. Default value is **false**.
sendCacheControlHeader	Optional **Boolean** attribute. Gets or sets a value indicating whether the **cache-control:private** header is sent by the output cache module by default. Default value is **false**.
omitVaryStar	Optional **Boolean** attribute. Enables/disables sending an Http "**Vary: ** *" header in the response. With the default setting of false, a* "***Vary: *" header is sent for output cached pages. When the Vary header is sent, it allows for different versions to be cached based upon what is specified in the Vary header. For example, *Vary:User-Agents* will store different versions of a page based upon the user agent issuing the request. Default value is **false.**

The <outputCacheSettings> Element

The <outputCacheSettings> element allows for the creation of cache profiles as previously described. The only child element for the <outputCacheSettings> element is the <outputCacheProfiles> element for configuring cache profiles.

The <sqlCacheDependency> Element

The following attributes are available for the <sqlCacheDependency> element.

ATTRIBUTE	DESCRIPTION
enabled	Required **Boolean** attribute. Indicates whether or not changes are being polled for.
pollTime	Optional **Int32** attribute. Sets the frequency with which the SqlCacheDependency polls the database table for changes. This value corresponds to the number of milliseconds between successive pollings. It cannot be set to less than 500 milliseconds. Default value is 1 minute.

More Information

There is some additional information that you should be aware of regarding cache configuration.

- If the worker process private bytes limit is not set, the cache will use one of the following limits:
  - x86 2GB: 800MB or 60% of physical RAM, whichever is less
  - x86 3GB: 1800MB or 60% of physical RAM, whichever is less
  - x64: 1 terabyte or 60% of physical RAM, whichever is less
- If both the worker process private bytes limit and <cache privateBytesLimit/> are set, the cache will use the minimum of the two.

- Just like in 1.x, we drop cache entries and call GC.Collect for two reasons:
  - We are very close to the private bytes limit
  - The available memory is near or less than 10%
- You can effectively disable trim and cache for low available memory conditions by setting <cache percentagePhysicalMemoryUseLimit/> to 100.
- Unlike 1.x, 2.0 will suspend the trim and collect calls if the last GC.Collect did not reduce private bytes or the size of the managed heaps by more than 1% of the (cache) memory limit.

Lab1: Custom Cache Dependencies

1. Create a new Web site.
2. Add a new XML file called cache.xml and save it to the root of the Web application.
3. Add the following code to the Page_Load method in the code-behind of default.aspx:

```
System.Web.Caching.CacheDependency dep = new
    System.Web.Caching.CacheDependency(Server.MapPath("cache.xml"));
Response.AddCacheDependency(dep);
Cache.Insert("time", DateTime.Now.ToString());
Response.Write(Cache["time"]);
```

4. Add the following to the top of default.aspx in source view:

```
<%@ OutputCache Duration="240" VaryByParam="None" %>
```

5. Browse Default.aspx. What does the time say?
6. Refresh the browser. What does the time say?
7. Open cache.xml and add the following code:

```
<anElement></anElement>
```

8. Save cache.xml.
9. Refresh your browser. What does the time say?
10. Explain why the time updated instead of displaying the previously cached values:

Lab 2: Using Polling-Based Cache Dependencies

This lab uses the project you created in the previous module that allows for editing of data in the Northwind database via a GridView and DetailsView control.

1. Open the project in Visual Studio 2005.
2. Run the aspnet_regsql utility against the Northwind database to enable the database and the Products table. Use the following command from a Visual Studio Command Prompt:

```
aspnet_regsql -S server -ed -d Northwind -E -et -t Products
```

3. Add the following to your web.config file:

```
<caching>
    <sqlCacheDependency enabled = "true" pollTime = "60000" >
        <databases>
            <add name="Northwind" connectionStringName = "Northwind" pollTime = "9000000" />
        </databases>
    </sqlCacheDependency>
</caching>
```

4. Add a new webform called showdata.aspx.
5. Add the following @ outputcache directive to the showdata.aspx page:

```
<%@ OutputCache SqlDependency="Northwind:Products" Duration="480" VaryByParam="None"%>
```

6. Add the following code to the Page_Load of showdata.aspx:

```
Response.Write(DateTime.Now.ToString() + "<br><br>");
```

7. Add a new SqlDataSource control to showdata.aspx and configure it to use the Northwind database connection. Click Next.
8. Select the ProductName and ProductID checkboxes and click Next.
9. Click Finish.
10. Add a new GridView to the showdata.aspx page.
11. Choose SqlDataSource1 from the dropdown.
12. Save and browse showdata.aspx. Make note of the time displayed.

Membership

by Microsoft

> ASP.NET Membership builds on the success of the Forms authentication model from ASP.NET 1.x. ASP.NET Forms authentication provides a convenient way to incorporate a login form into your ASP.NET application and validate users against a database or other data store.

ASP.NET Membership builds on the success of the Forms authentication model from ASP.NET 1.x. ASP.NET Forms authentication provides a convenient way to incorporate a login form into your ASP.NET application and validate users against a database or other data store. The members of the FormsAuthentication class make it possible to handle cookies for authentication, check for a valid login, log a user out etc. However, implementing Forms authentication in an ASP.NET 1.x application can require a fair amount of code.

Membership in ASP.NET 2.0 is a major advancement over using Forms authentication alone. (Membership is most robust when coupled with Forms authentication, but using Forms authentication is not a requirement.) As you'll soon see, you can use ASP.NET Membership and the login controls in ASP.NET 2.0 to implement a powerful membership system without writing much code at all.

Implementing Membership in ASP.NET 2.0

Membership is implemented by following four steps. Keep in mind that there are many sub-steps that are involved as well as optional configuration that can be implemented as well. These steps are meant to illustrate the big picture of configuring membership.

1. Create your membership database (if SQL Server is used as the membership store.)
2. Specify the membership options in your applications configuration files. (Membership is enabled by default.)
3. Determine the type of membership store you want to use. Options are:
   - Microsoft SQL Server (version 7.0 or later)
   - Active Directory Store
   - Custom membership provider
4. Configure the application for ASP.NET Forms authentication. Once again, Membership is designed to take advantage of Forms authentication, but using Forms authentication is not a requirement.
5. Define user accounts for membership and configure roles if desired.

Creating the Membership Database

If you're using SQL Server 7.0 or later as your membership store, you can use the aspnet_regsql utility (available most easily from the Visual Studio .NET 2005 Command Prompt) to configure your database. The aspnet_regsql utility can be used as a command prompt tool or via a GUI wizard. The wizard method is the easiest way to configure your database. To access the wizard, simply run the following command:

```
aspnet_regsql W
```

Once you run that command, you will be presented with the ASP.NET SQL Server Setup Wizard as shown below.

Figure 1

The ASP.NET SQL Server Setup Wizard creates the Web site in the instance you specify in the wizard. However, ASP.NET will use the connection string in the machine.config file to connect to your database. By default, this connection string will point to a SQL Server 2005 instance, so if you are using a SQL Server 2000 or SQL Server 7.0 instance, you will need to modify the connection string in the machine.config file. That connection string can be located here:

```
<configuration>
    <connectionStrings>
      <add name="LocalSqlServer"
         connectionString="data source=(local);
         Integrated Security=SSPI;Initial Catalog=aspnetdb;"
         providerName="System.Data.SqlClient" />
    </connectionStrings>
</configuration>
```

Unfortunately, if you don't modify the connection string, ASP.NET will not give you a descriptive error. It will just continue to complain saying that you haven't created the database. In the case above, I have modified the connection string to point to my local SQL Server 2000 instance.

Specifying Configuration and Adding Users and Roles

The next step in configuring Membership is to add the necessary information to the web.config file of the application. In ASP.NET 1.x, modifying the web.config file was sometimes difficult because of the use of lowerCamelCase and the lack of Intellisense. Visual Studio .NET 2005 makes the task much easier with Intellisense for configuration files, but ASP.NET 2.0 goes one step further by providing a Web interface for editing configuration files.

You can launch the Web interface by clicking the ASP.NET Configuration button on the Solution Explorer toolbar as shown below. You can also launch the Web interface via pop-ups that are displayed when Login controls are inserted.

Figure 2

This launches the ASP.NET Web Site Administration Tool shown below. The ASP.NET Web Site Administration is a four-tab interface that makes it easy to manage application settings. The following tabs are available:

- **Home**
- **Security** Configure users, roles, and access.
- **Application** Configure application settings.
- **Provider** Configure and test your applications membership provider.

The Web Site Administration Tool allows you to easily create new users, create new roles, and to manage users and roles. This ability is not available in the Windows interface. The Windows interface allows you to easily define authorization settings and to add, delete, and manage providers, capabilities that are not in the Web Site Administration Tool.

To launch the Windows interface, open the Internet Information Services snap-in, right-click on your application, and choose Properties. Click the ASP.NET tab and then click the Edit Configuration button. (The application must be running under ASP.NET 2.0 for the Edit Configuration button to be enabled. You can configure the ASP.NET version in the ASP.NET dialog as well.) The ASP.NET Configuration Settings dialog is displayed as shown below.

Figure 3

On the General tab, connection strings and application settings are listed. Any settings in italics are defined in a parent configuration file (either the machine.config or a web.config at a higher level) and settings not in italics are from the applications configuration file. If a setting is added, removed, or edited at the application level, ASP.NET will add, remove, or modify the setting at the application levels web.config instead of removing the setting from the configuration file from which it is inherited.

The Authentication tab is shown below. This is where you will configure your membership settings. Forms authentication settings, membership providers, and role providers can be configured here.

Figure 4

Implementing Membership in Your Application

The easiest way to implement ASP.NET 2.0 membership in your application is to use the provided Logon controls. This method allows you to implement the basics of ASP.NET 2.0 membership without writing any code at all.

The following Logon controls are available in ASP.NET 2.0:

Login Control

The Login control provides an interface for someone to log into your membership system. It provides you with a username and password textbox and a login button. Many other common features such as a link to register for people who have not yet done so, a checkbox that allows the user to automatically login on subsequent visits, a link for a password reminder, etc. All features of the Login control are customizable via the properties of the control.

In ASP.NET 1.x, developers had to write a fair amount of code to do a lookup when using Forms authentication. With ASP.NET 2.0 membership, you can validate users without writing any code at all. ASP.NET will automatically do the look-up of the user for you. (If you are using the Login control without using ASP.NET membership, you can use the **OnAuthenticate** method to validate the user.)

LoginView Control

The LoginView control is a templated control that provides two templates by default; the AnonymousTemplate and the LoggedInTemplate. The template that is displayed is determined by whether or not the user is logged into your membership system. This control is typically used to display a Login control when a user has not yet logged in and a LoginStatus control and/or other login controls when the user has logged in. If you are using role management in your ASP.NET application, the LoginView control can display a specific template based upon the users role. (More on ASP.NET role management will be covered later.)

PasswordRecovery Control

The PasswordRecovery control allows users to receive an email with his or her current password or reset his or her password. Clear text and encrypted passwords can be recovered and emailed to users. If the password is hashed, it

cannot be recovered. Instead the user will be required to perform a password reset.

LoginStatus Control

The LoginStatus control is used to display a login indicator to users who are not logged in and a logout indicator to users who are currently logged in. The Request.IsAuthenticated property is used to determine which indicator to display. The indicator displayed by the LoginStatus control can be text (implemented via the **LoginText** and **LogoutText** properties) or images (implemented via the **LoginImageUrl** and **LogoutImageUrl** properties.)

When a user logs out via the LoginStatus control, he or she is redirected to the URL specified by the **LogoutPageUrl** property. If that property is not set, the current page is refreshed. Since the site is likely protected by Forms authentication, the refresh of the current page will redirect the user to the login page for the site.

LoginName Control

The LoginName control displays the username of the user currently logged into the site.

CreateUserWizard Control

The CreateUserWizard control provides users with a convenient way to register for your membership system. You can add steps (implemented as a collection of WizardSteps) via the interface shown below.

Figure 5

The CreateUserWizard is a templated control that derives from the Wizard class and provides the following templates:

- **HeaderTemplate** This template controls the appearance of the header of the wizard.
- **SidebarTemplate** This template controls the appearance of the sidebar of the wizard.
- **StartNavigationTemplate** This template controls the appearance of the navigation are of the wizard at the start step.
- **StepNavigationTemplate** This template controls the appearance of the navigation area when not in the start or finish step.
- **FinishNavigationTemplate** This template controls the appearance of the navigation area when on the finish step.

Additionally, for each step that you add to the Wizard, ASP.NET will create a custom template that contains both a ContentTemplate and a CustomNavigationTemplate for that step. For full details on customizing the CreateUserWizard, see the VS.NET 2005 documentation:

ChangePassword Control

The ChangePassword control allows users to change his or her password. If the DisplayUserName property is true (it is false by default), the user can change his or her password when they are not logged in. If the user *is* already logged in and the DisplayUserName property is true, the user will be able to change the password of another user that is not logged in providing they know the user ID of that user.

Keep in mind that if you want users to be able to change passwords without having to log in, you will need to ensure that the page on which the ChangePassword control is displayed allows anonymous access. Obviously, users will have to provide their old password in order to change their password.

Role Management

Role management allows you to assign users to a particular role and then restrict access to certain file or folders based on that role. Role management also provides an API so that you can programmatically determine someones role or determine all users in a particular role and respond accordingly.

Role management is not a requirement in ASP.NET membership, nor is membership a requirement in order to use role management. However, the two supplement each other nicely and it is likely that developers will use them in conjunction with each other.

To enable role management in your application, make the following change in your web.config file:

```
<roleManager enabled="true" cacheRolesInCookie="true" cookieProtection="All" />
```

When the **cacheRolesInCookie** attribute is set to true, ASP.NET caches a users role membership in a cookie on the client. This allows role lookups to occur without calls into the RoleProvider. When using this attribute, developers are encouraged to ensure that the **cookieProtection** attribute is set to All. (This is the default setting.) This ensures that the cookie data are encrypted and helps to ensure that the cookies contents haven't been altered. Roles can be added using the Web Site Administration Tool. It allows you to easily define roles, configure access to parts of the site based on those roles, and assign users to roles.

Figure 6

As shown above, new roles can be added by simply entering the name of the role and then clicking Add Role. Existing roles can be managed or deleted by clicking the appropriate link in the list of existing roles.

When you manage a role, you can add or remove users as shown below.

Figure 7

By checking the User Is In Role checkbox, you can easily add a user to a specific role. ASP.NET will automatically update your membership database with the appropriate entries. You will also want to configure access rules for your application. ASP.NET 1.x developers are familiar with doing this via the <authorization> element in the web.config file, and that option is still available in ASP.NET 2.0. However, its easier to manage access rules using the Web Site Administration Tool as shown below.

Figure 8

In this case, the Administration folder is highlighted (its difficult to see because the tool highlights it in light gray) and the Administrators role has been granted access. All other users are denied. You can click on the head icon to select a rule and then use the Move Up and Move Down buttons to arrange the rules. As with the ASP.NET <authorization> element, rules are processed in the order in which they appear. In other words, if the order of rules in the shot above were reversed, no one would have access to the Administration folder because the first rule that ASP.NET would encounter would be the rule that denies everyone to the folder.

ASP.NET 2.0 adds a web.config file to the folder for which you are specifying an access rule. Access rules can be edited via the configuration file or via the Web Site Administration Tool. In other words, the Web Site Administration Tool is simply an interface through which the configuration file can be edited in a user-friendly environment.

Using Roles in Code

The API for role management has not changed since version 1.x. The **IsInRole** method is used to determine if a user is in a particular role.

```
if (User.IsInRole(Administrators)) {
    btnManageSite.Visible = true;
}
```

ASP.NET also creates a RolePrincipal instance as a member of the current context. The RolePrincipal object can be used to obtain all of the roles to which the user belongs as follows:

```
string[] userRoles = ((RolePrincipal)User).GetRoles();
```

Using RoleGroups with the LoginView Control

Now that you have an understanding of role management and membership, lets discuss briefly how the LoginView control takes advantage of this capability in ASP.NET 2.0. As previously discussed, the LoginView control is a templated control that contains two templates by default; the AnonymousTemplate and the LoggedInTemplate. Within the LoginView Tasks dialog is a link (shown below) that allows you to edit RoleGroups.

Figure 9

Each RoleGroup object contains an array of strings that defines which roles that RoleGroup applies to. To add a new RoleGroup to the LoginView control, click the Edit RoleGroups link. In the image above, you can see that I have added a new RoleGroup for Administrators. By selecting that RoleGroup (RoleGroup[0]) from the Views dropdown, I can configure a template that will only be displayed to members of the Administrators role. In the image below, I have added a new RoleGroup that applies to members of the Sales role and the Distribution role. This adds a second RoleGroup to the Views dropdown in the LoginView Tasks dialog and anything added to that template will be visible by any user in either the Sales or Distribution role.

Figure 10

Overriding the Existing Membership Provider

There are a couple of ways that you can extend the functionality of ASP.NET membership. First of all, you can obviously change the existing functionality of the SqlMembershipProvider class by inheriting from it and overriding its methods. For example, if you want to implement your own functionality when users are created, you can create your own class that inherits from SqlMembershipProvider as follows:

```
public class jForumMembershipProvider : SqlMembershipProvider {
    public jForumMembershipProvider() {

    }
    public override MembershipUser CreateUser(
    string username,
    string password,
    string email,
    string passwordQuestion,
    string passwordAnswer,
    bool isApproved,
    object providerUserKey,
    out MembershipCreateStatus status) {
        // your own implementation
        return base.CreateUser(
        username,
        password,
        email,
        passwordQuestion,
        passwordAnswer,
        isApproved,
        providerUserKey,
        out status);
    }
}
```

If, on the other hand, you want to create your own provider (to store your membership information in an Access database, for example), you can create your own provider.

Creating Your Own Membership Provider

To create your own membership provider, you will first need to create a class that inherits from the MembershipProvider class. If you are using VB.NET, Visual Studio 2005 will add the stubs for all of the methods

that you need to override. If you are using C#, its up to you to add the stubs.

You will need to override the following:

- ApplicationName property
- ChangePassword function
- ChangePasswordQuestionAndAnswer function
- CreateUser function
- DeleteUser function
- EnablePasswordReset property
- EnablePasswordRetrieval property
- FindUsersByEmail function
- FindUsersByName function
- GetAllUsers function
- GetNumberOfUsersOnline function
- GetPassword function
- GetUser function
- GetUserNameByEmail function
- MaxInvalidPasswordAttempts property
- MinRequiredNonAlphanumericCharacters property
- MinRequiredPasswordLength property
- PasswordAttemptWindow property
- PasswordFormat property
- PasswordStrengthRegularExpression property
- RequiresQuestionAndAnswer property
- RequiresUniqueEmail property
- ResetPassword function
- Unlock user function
- UpdateUser function
- ValidateUser function

Thats quite a list to implement as a C# developer. You may find it easier to create the class in VB.NET without any implementation and then use .NET Reflector or a similar tool to convert the code to C#.

The connection string and other properties should be set to their defaults in the Initialize method. (The Initialize method is fired when the provider is loaded at runtime.) The second parameter to the Initialize method is of type System.Collections.Specialized.NameValueCollection and is a reference to the <add> element that is associated with your custom provider in the web.config file. That entry looks like the following:

```
<system.web>
  <authentication mode="Forms"/>
  <membership
  defaultProvider="jForumCustomMembershipProvider" >
    <providers>
      <add name="jForumCustomMembershipProvider"
      type="jForumCustomMembershipProvider"
      requiresQuestionAndAnswer="true"
      connectionString="Provider=Microsoft.Jet.
        OLEDB.4.0;Data Source=C:\jForumCustomMembershipProvider\
        App_Data\Members.mdb;Persist Security
        Info=False"
        />
    </providers>
  </membership>
</system.web>
```

Here is an example of the Initialize method.

```
public override void Initialize(string name,
    System.Collections.Specialized.NameValueCollection config) {

    if (config["requiresQuestionAndAnswer"])
        _requiresQuestionAndAnswer = true;
    _connString = config["connectionString"];
    base.Initialize(name, config);
}
```

In order to validate the user when they submit your login form, you will need to use the ValidateUser method. This method fires when the user clicks the login button in the Login control. You will place your code that does the user lookup in this method.

As you can see, writing your own membership provider is not difficult and allows you to extend this powerful functionality of ASP.NET 2.0.

Configuration and Instrumentation

4/10/2020 • 30 minutes to read • Edit Online

There are major changes in configuration and instrumentation in ASP.NET 2.0. The new ASP.NET configuration API allows for configuration changes to be made programmatically. In addition, many new configuration settings exist allow for new configurations and instrumentation.

In this module, we will discuss ASP.NET the configuration API as it relates to reading from and writing to ASP.NET configuration files, and we will also cover ASP.NET instrumentation. We will also cover the new features available in ASP.NET tracing.

ASP.NET Configuration API

The ASP.NET configuration API allows you to develop, deploy, and manage application configuration data by using a single programming interface. You can use the configuration API to develop and modify complete ASP.NET configurations programmatically without directly editing the XML in the configuration files. In addition, you can use the configuration API in console applications and scripts that you develop, in Web-based management tools, and in Microsoft Management Console (MMC) snap-ins.

The following two configuration-management tools use the configuration API and are included with the .NET Framework version 2.0:

- The ASP.NET MMC snap-in, which uses the configuration API to simplify administrative tasks, providing an integrated view of local configuration data from all levels of the configuration hierarchy.
- The Web Site Administration Tool, which allows you to manage configuration settings for local and remote applications, including hosted sites.

The ASP.NET configuration API comprises a set of ASP.NET management objects that you can use to configure Web sites and applications programmatically. Management objects are implemented as a .NET Framework class library. The configuration API programming model helps ensure code consistency and reliability by enforcing data types at compile time. To make it easier to manage application configurations, the configuration API allows you to view data that is merged from all points in the configuration hierarchy as a single collection, instead of viewing the data as separate collections from different configuration files. Additionally, the configuration API enables you to manipulate entire application configurations without directly editing the XML in the configuration files. Finally, the API simplifies configuration tasks by supporting administrative tools, such as the Web Site Administration Tool. The configuration API simplifies deployment by supporting the creation of configuration files on a computer and running configuration scripts across multiple computers.

> **NOTE**
>
> The configuration API does not support the creation of IIS applications.

Working with Local and Remote Configuration Settings

A Configuration object represents the merged view of the configuration settings that apply to a specific physical entity, such as a computer, or to a logical entity, such as an application or a Web site. The specified logical entity can exist on the local computer or on a remote server. When no configuration file exists for a specified entity, the Configuration object represents the default configuration settings as defined by the Machine.config file.

You can get a Configuration object by using one of the open configuration methods from the following classes:

1. The ConfigurationManager class, if your entity is a client application.
2. The WebConfigurationManager class, if your entity is a Web application.

These methods will return a Configuration object, which in turn provides the required methods and properties to handle the underlying configuration files. You can access these files for reading or writing.

Reading

You use the GetSection or GetSectionGroup method to read configuration information. The user or process that reads must have Read permissions on all of the configuration files in the hierarchy.

> **NOTE**
>
> If you use a static GetSection method that takes a path parameter, the path parameter must refer to the application in which the code is running. Otherwise, the parameter is ignored and the configuration information for the currently running application is returned.

Writing

You use one of the Save methods to write configuration information. The user or process that writes must have Write permissions on the configuration file and directory at the current configuration hierarchy level, as well as Read permissions on all of the configuration files in the hierarchy.

To generate a configuration file that represents the inherited configuration settings for a specified entity, use one of the following save-configuration methods:

1. The Save method to create a new configuration file.
2. The SaveAs method to generate a new configuration file at another location.

Configuration Classes and Namespaces

Many configuration classes and methods are similar to each other. The following table describes the most commonly used configuration classes and namespaces.

CONFIGURATION CLASS OR NAMESPACE	DESCRIPTION
System.Configuration namespace	Contains the main configuration classes for all .NET Framework applications. Section handler classes are used to obtain configuration data for a section from methods, such as GetSection and GetSectionGroup. These two methods are non-static.
System.Configuration.Configuration class	Represents a set of configuration data for a computer, application, Web directory, or other resource. This class contains useful methods, such as GetSection and GetSectionGroup, for updating configuration settings and obtaining references to sections and section groups. This class is used as a return type for methods that obtain design-time configuration data, such as the methods of the WebConfigurationManager and ConfigurationManager classes.

CONFIGURATION CLASS OR NAMESPACE	DESCRIPTION
System.Web.Configuration namespace	Contains the section handler classes for the ASP.NET configuration sections defined at ASP.NET Configuration Settings. Section handler classes are used to obtain configuration data for a section from methods, such as GetSection and GetSectionGroup.
System.Web.Configuration.WebConfigurationManager class	Provides useful methods for obtaining references to run-time and design-time configuration settings. These methods use the System.Configuration.Configuration class as a return type. You can use the static GetSection method of this class or the non-static GetSection method of the System.Configuration.ConfigurationManager class interchangeably. For Web application configurations, the System.Web.Configuration.WebConfigurationManager class is recommended instead of the System.Configuration.ConfigurationManager class.
System.Configuration.Provider namespace	Provides a way to customize and extend the configuration provider. This is the base class for all provider classes in the configuration system.
System.Web.Management namespace	Contains classes and interfaces for managing and monitoring the health of Web applications. Strictly speaking, this namespace is not considered part of the configuration API. For example, tracing and event firing is accomplished by the classes in this namespace.
System.Management.Instrumentation namespace	Provides the classes necessary for the instrumentation of applications to expose their management information and events through Windows Management Instrumentation (WMI) to potential consumers. ASP.NET health monitoring uses WMI to deliver events. Strictly speaking, this namespace is not considered part of the configuration API.

Reading from ASP.NET Configuration Files

The WebConfigurationManager class is the core class for reading from ASP.NET configuration files. There are essentially three steps to reading ASP.NET configuration files:

1. Get a Configuration object using the OpenWebConfiguration method.
2. Get a reference to the desired section in the configuration file.
3. Read the desired information from the configuration file.

The Configuration object represents does not represent a particular configuration file. Instead, it represents a merged view of the configuration of a computer, application, or Web site. The following code sample instantiates a Configuration object representing the configuration of a Web application called *ProductInfo*.

```
Configuration config = WebConfigurationManager.OpenWebConfiguration("/ProductInfo);
```

NOTE

Note that if the /ProductInfo path doesn't exist, the above code will return the default configuration as specified in the machine.config file.

Once you have the Configuration object, you can then use the GetSection or GetSectionGroup method to drill into the configuration settings. The following example gets a reference to the impersonation settings for the above ProductInfo application:

```
Configuration config =
    WebConfigurationManager.OpenWebConfiguration("/ProductInfo);
IdentitySection section =
   (IdentitySection)config.GetSection("system.web/identity");
```

Writing to ASP.NET Configuration Files

As in reading from configuration files, the WebConfigurationManager class is the core for writing to Asp.NET configuration files. There are also three steps to writing to ASP.NET configuration files.

1. Get a Configuration object using the OpenWebConfiguration method.
2. Get a reference to the desired section in the configuration file.
3. Write the desired information from the configuration file using the Save or SaveAs method.

The following code changes the **debug** attribute of the <compilation> element to false:

```
System.Configuration.Configuration updateWebConfig =
    System.Web.Configuration.WebConfigurationManager.OpenWebConfiguration("/webApp");

System.Web.Configuration.CompilationSection compilation =
    updateWebConfig.GetSection("system.web/compilation")
    as System.Web.Configuration.CompilationSection;

compilation.Debug = false;

if (!compilation.SectionInformation.IsLocked) {
    updateWebConfig.Save();
    Response.Write("Save Success!");
} else {
    Response.Write("Save Failed!");
}
```

When this code is executed, the **debug** attribute of the <compilation> element will be set to false for the *webApp* application's web.config file.

System.Web.Management Namespace

The System.Web.Management namespace provides the classes and interfaces for managing and monitoring the health of ASP.NET applications.

Logging is accomplished by defining a rule that associates events with a provider. The rule defines the type of events that are sent to the provider. The following base events are available for you to log:

WEBBASEEVENT	THE BASE EVENT CLASS FOR ALL EVENTS. CONTAINS THE REQUIRED PROPERTIES FOR ALL EVENTS SUCH AS EVENT CODE, EVENT DETAIL CODE, THE DATE AND TIME THE EVENT WAS RAISED, SEQUENCE NUMBER, THE EVENT MESSAGE, AND EVENT DETAILS.
WebManagementEvent	The base event class for management events, such as application lifetime, request, error, and audit events.
WebHeartbeatEvent	The event generated by the application in regular intervals to capture useful runtime state information.

WEBBASEEVENT	THE BASE EVENT CLASS FOR ALL EVENTS. CONTAINS THE REQUIRED PROPERTIES FOR ALL EVENTS SUCH AS EVENT CODE, EVENT DETAIL CODE, THE DATE AND TIME THE EVENT WAS RAISED, SEQUENCE NUMBER, THE EVENT MESSAGE, AND EVENT DETAILS.
WebAuditEvent	The base class for security audit events, which are used to mark conditions such as authorization failure, decryption failure, *etc.*
WebRequestEvent	The base class for all informational request events.
WebBaseErrorEvent	The base class for all events indicating error conditions.

The types of providers available allow you to send event output to Event Viewer, SQL Server, Windows Management Instrumentation (WMI), and email. The pre-configured providers and event mappings reduce the amount of work necessary to get event output logged.

ASP.NET 2.0 uses the Event Log provider out-of-the-box to log events based on application domains starting and stopping, as well as logging any unhandled exceptions. This helps to cover some of the basic scenarios. For example, let's say that your application throws an exception, but the user doesn't save the error and you can't reproduce it. With the default Event Log rule, you would be able to gather the exception and stack information to get a better idea of what kind of error occurred. Another example applies if your application is losing session state. In that case, you can look in the Event Log to determine whether the application domain is recycling, and why the application domain stopped in the first place.

Also, the health monitoring system is extensible. For example, you can define custom Web events, fire them within your application, and then define a rule to send the event information to a provider such as your email. This allows you to easily tie your instrumentation to the health monitoring providers. As another example, you could fire an event each time an order is processed and set up a rule that sends each event to the SQL Server database. You could also fire an event when a user fails to log on multiple times in a row, and set up the event to use the email-based providers.

The configuration for the default providers and events is stored in the global Web.config file. The global Web.config file stores all the Web-based settings that were stored in the Machine.config file in ASP.NET 1x. The global Web.config file is located in the following directory:

```
%windir%\Microsoft.Net\Framework\v2.0.*\config\Web.config
```

The <healthMonitoring> section of the global Web.config file provides default configuration settings. You can override these setting or configure your own settings by implementing the <healthMonitoring> section in the Web.config file for your application.

The <healthMonitoring> section of the global Web.config file contains the following items:

PROVIDERS	CONTAINS PROVIDERS SET UP FOR THE EVENT VIEWER, WMI, AND SQL SERVER.
eventMappings	Contains mappings for the various WebBase classes. You can extend this list if you generate your own event class. Generating your own event class gives you finer granularity over the providers you send information to. For example, you could configure unhandled exceptions to be sent to SQL Server, while sending your own custom events to email.
rules	Links the eventMappings to the provider.

PROVIDERS	CONTAINS PROVIDERS SET UP FOR THE EVENT VIEWER, WMI, AND SQL SERVER.
buffering	Used with SQL Server and email providers to determine how often to flush the events to the provider.

Below is a code example from the global Web.config file.

```
<healthMonitoring>
  <!-- Event Log Provider being added. -->
  <providers>
    <add name="EventLogProvider"
         type="System.Web.Management.EventLogWebEventProvider,
               System.Web,Version=2.0.0.0,Culture=neutral,
               PublicKeyToken=b03f5f7f11d50a3a" />
  </providers>
  <!-- Event mapping provides a friendly name to the
events based on the WebBaseErrorEvent class. -->
  <eventMappings>
    <add name="All Errors"
         type="System.Web.Management.WebBaseErrorEvent,
               System.Web,Version=2.0.0.0,Culture=neutral,
               PublicKeyToken=b03f5f7f11d50a3a"
          startEventCode="0" endEventCode="2147483647" />
  </eventMappings>
  <!-- Rule tying the "All Errors" event mapping to the EventLog Provider. -->
  <rules>
    <add name="All Errors Default" eventName="All Errors"
         provider="EventLogProvider"
         profile="Default" minInstances="1"
         maxLimit="Infinite" minInterval="00:01:00" custom="" />
  </rules>
</healthMonitoring>
```

How to store events to Event Viewer

As mentioned earlier, the provider for logging events in the Event Viewer is configured for you in the global Web.config file. By default, all events based on **WebBaseErrorEvent** and **WebFailureAuditEvent** are logged. You can add additional rules to log additional information to the Event Log. For example, if you wanted to log all events (*i.e.*, every event based on **WebBaseEvent**), you could add the following rule to your Web.config file:

```
<healthMonitoring>
    <rules>
        <add name="All Events" eventName="All Events"
             provider="EventLogProvider" profile="Critical" />
    </rules>
</healthMonitoring>
```

This rule would link the **All Events** event map to the Event Log provider. Both eventMapping and the provider are included in the global Web.config file.

How to store events to SQL Server

This method uses the **ASPNETDB** database, which is generated by the Aspnet_regsql.exe tool. The default provider uses the LocalSqlServer connection string, which uses either a file-based database in the App_data folder or the local SQLExpress instance of SQL Server. Both the LocalSqlServer connection string and the SqlProvider are configured in the global Web.config file.

The LocalSqlServer connection string in the global Web.config file looks like this:

```
<connectionStrings>
    <add name="LocalSqlServer"
         connectionString="data source=.\SQLEXPRESS;
         Integrated Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;
         User Instance=true"
         providerName="System.Data.SqlClient" />
</connectionStrings>
```

If you want to use another SQL Server instance, you'll need to use the Aspnet_regsql.exe tool, which can be found in the %windir%\Microsoft.Net\Framework\v2.0.* folder. Use the Aspnet_regsql.exe tool to generate a custom **ASPNETDB** database on the SQL Server instance, then add the connection string to your applications configuration file, and then add a provider by using the new connection string. Once you have the **ASPNETDB** database created, you'll need to set a rule to link an eventMapping to the sqlProvider.

Whether you use the default SqlProvider or configure your own provider, you'll need to add a rule linking the provider with an event map. The following rule links the new provider that you created above to the **All Events** event map. This rule will log all the events based on **WebBaseEvent** and send them to the MySqlWebEventProvider that will use the MYASPNETDB connection string. The following code adds a rule to link the provider with an event map:

```
<healthMonitoring>
    <rules>
        <add name="All Events" eventName="All Events"
        provider="MySqlWebEventProvider" profile="Critical"/>
    </rules>
</healthMonitoring>
```

If you wanted to only send errors to SQL Server, you could add the following rule:

```
<add name="All Errors"
    eventName="All Errors"
    provider="MySqlWebEventProvider"
    profile="Critical"/>
```

How to forward events to WMI

You can also forward the events to WMI. The WMI provider is configured for you in the global Web.config file by default.

The following code example adds a rule to forward the events to WMI:

```
<providers>
    <add name="WmiWebEventProvider"
      type="System.Web.Management.WmiWebEventProvider,System.Web,
         Version=2.0.0.0,Culture=neutral,
         PublicKeyToken=b03f5f7f11d50a3a" />
</providers>
```

You will need to add a rule to associate an eventMapping to the provider, and also a WMI listener application to listen for the events. The following code example adds a rule to link the WMI provider to the **All Events** event map:

```
<rules>
    <add name="All Events"
      eventName="All Events" provider="WmiWebEventProvider"
        profile="Critical" />
</rules>
```

How to forward events to email

You can also forward events to email. Be careful about which event rules you map to your email provider, as you can unintentionally send yourself a lot of information that may be better suited for SQL Server or the Event Log. There are two email providers; SimpleMailWebEventProvider and TemplatedMailWebEventProvider. Each has the same configuration attributes, with the exception of the "template" and "detailedTemplateErrors" attributes, both of which are only available on the TemplatedMailWebEventProvider.

> **NOTE**
> Neither of these email providers is configured for you. You'll need to add them to your Web.config file.

The main difference between these two email providers is that SimpleMailWebEventProvider sends emails in a generic template that cannot be modified. The sample Web.config file adds this email provider to the list of configured providers by using the following rule:

```
<add name="mySimple-mailWebEventProvider"
     type="System.Web.Management.Simple-mailWebEventProvider"
     to="e-mail@foo.com" from="e-mail@foo.com"
     maxMessagesPerNotification="1" maxEventsPerMessage="10"
     buffer="true" bufferMode="Critical Notification"
     subjectPrefix="Web Events"/>
```

The following rule is also added to tie the email provider to the **All Events** event map:

```
<add name="All Events" eventName="All Events"
    provider="mySimple-mailWebEventProvider" profile="Critical"/>
```

ASP.NET 2.0 Tracing

There are three major enhancements to tracing in ASP.NET 2.0.

1. Integrated tracing functionality
2. Programmatic access to trace messages
3. Improved application-level tracing

Integrated Tracing Functionality

You can now route messages emitted by the System.Diagnostics.Trace class to ASP.NET tracing output, and route messages emitted by ASP.NET tracing to System.Diagnostics.Trace. You can also forward ASP.NET instrumentation events to System.Diagnostics.Trace. This functionality is provided by the new **writeToDiagnosticsTrace** attribute of the <trace> element. When this Boolean value is true, ASP.NET Trace messages are forwarded to the System.Diagnostics tracing infrastructure for use by any listeners that are registered to display Trace messages.

Programmatic Access to Trace Messages

ASP.NET 2.0 allows for programmatic access to all trace messages via the **TraceContextRecord** class and the **TraceRecords** collection. The most efficient way of accessing trace messages is to register a **TraceContextEventHandler** delegate (also new in ASP.NET 2.0) to handle the new **TraceFinished** event. You can then loop through the trace messages as you wish.

The following code sample illustrates this:

```
void Page_Load(object sender, EventArgs e) {
    // Register a handler for the TraceFinished event.
    Trace.TraceFinished += new
        TraceContextEventHandler(this.OnTraceFinished);
    // Write a trace message.
    Trace.Write("Web Forms Infrastructure Methods",
      "USERMESSAGE: Page_Load complete.");
}

// A TraceContextEventHandler for the TraceFinished event.
void OnTraceFinished(object sender, TraceContextEventArgs e) {
    TraceContextRecord r = null;
    // Iterate through the collection of trace records and write
    // them to the response stream.
    foreach (object o in e.TraceRecords) {
        r = (TraceContextRecord)o;
        Response.Write(String.Format("trace message: {0} <BR>",
        r.Message));
    }
}
```

In the above example, I loop through the TraceRecords collection and then write each message to the Response stream.

Improved Application-Level Tracing

Application-level tracing is improved via the introduction of the new **mostRecent** attribute of the <trace> element. This attribute specifies whether the most recent application-level tracing output is displayed and older trace data beyond the limits that are indicated by the requestLimit are discarded. If false, trace data are displayed for requests until the requestLimit attribute is reached.

ASP.NET Command Line Tools

There are several command-line tools to aid in configuration of ASP.NET. ASP.NET developers should be familiar with the aspnet_regiis.exe tool. ASP.NET 2.0 provides three other command-line tools to aid in configuration.

The following command-line tools are available:

TOOL	USE
aspnet_regiis.exe	Allows for registration of ASP.NET with IIS. There are two versions of this tools that ship with ASP.NET 2.0, one for 32-bit systems (in the Framework folder) and one for 64-bit systems (in the Framework64 folder.) The 64-bit version will not be installed on a 32-bit OS.
aspnet_regsql.exe	The ASP.NET SQL Server Registration tool is used to create a Microsoft SQL Server database for use by the SQL Server providers in ASP.NET, or to add or remove options from an existing database. The Aspnet_regsql.exe file is located in the [drive:]\WINDOWS\Microsoft.NET\Framework\versionNumber folder on your Web server.

TOOL	USE
aspnet_regbrowsers.exe	The ASP.NET Browser Registration tool parses and compiles all system-wide browser definitions into an assembly and installs the assembly into the global assembly cache. The tool uses the browser definition files (.BROWSER files) from the .NET Framework Browsers subdirectory. The tool can be found in the %SystemRoot%\Microsoft.NET\Framework\version\ directory.
aspnet_compiler.exe	The ASP.NET Compilation tool enables you to compile an ASP.NET Web application, either in place or for deployment to a target location such as a production server. In-place compilation helps application performance because end users do not encounter a delay on the first request to the application while the application is compiled.

Because the aspnet_regiis.exe tool is not new to ASP.NET 2.0, we will not discuss it here.

ASP.NET SQL Server Registration Tool - aspnet_regsql.exe

You can set several types of options using the ASP.NET SQL Server Registration tool. You can specify a SQL connection, specify which ASP.NET application services use SQL Server to manage information, indicate which database or table is used for SQL cache dependency, and add or remove support for using SQL Server to store procedures and session state.

Several ASP.NET application services rely on a provider to manage storing and retrieving data from a data source. Each provider is specific to the data source. ASP.NET includes a SQL Server provider for the following ASP.NET features:

- Membership (the SqlMembershipProvider class).
- Role Management (the SqlRoleProvider class).
- Profile (the SqlProfileProvider class).
- Web Parts Personalization (the SqlPersonalizationProvider class).
- Web Events (the SqlWebEventProvider class).

When you install ASP.NET, the Machine.config file for your server includes configuration elements that specify SQL Server providers for each of the ASP.NET features that rely on a provider. These providers are configured, by default, to connect to a local user instance of SQL Server Express 2005. If you change the default connection string used by the providers, then before you can use any of the ASP.NET features configured in the machine configuration, you must install the SQL Server database and the database elements for your chosen feature using Aspnet_regsql.exe. If the database that you specify with the SQL registration tool does not already exist (aspnetdb will be the default database if one is not specified on the command line), then the current user must have rights to create databases in SQL Server as well as to create schema elements within a database.

SQL Cache Dependency

An advanced feature of ASP.NET output caching is SQL cache dependency. SQL cache dependency supports two different modes of operation: one that uses an ASP.NET implementation of table polling and a second mode that uses the query notification features of SQL Server 2005. The SQL registration tool can be used to configure the table-polling mode of operation.

Session State

By default, session state values and information are stored in memory within the ASP.NET process. Alternatively, you can store session data in a SQL Server database, where it can be shared by multiple Web servers. If the database that you specify for session state with the SQL registration tool does not already exist, then the current

user must have rights to create databases in SQL Server as well as to create schema elements within a database. If the database does exist, then the current user must have rights to create schema elements in the existing database.

To install the session state database on SQL Server, run the Aspnet_regsql.exe tool and supply the following information with the command:

- The name of the SQL Server instance, using the **-S** option.
- The logon credentials for an account that has permission to create a database on a computer running SQL Server. Use the **-E** option to use the currently logged-on user, or use the **-U** option to specify a user ID along with the **-P** option to specify a password.
- The **-ssadd** command-line option to add the session state database.

By default, you cannot use the Aspnet_regsql.exe tool to install the session state database on a computer running SQL Server 2005 Express Edition.

The ASP.NET Browser Registration Tool - aspnet_regbrowsers.exe

In ASP.NET version 1.1, the Machine.config file contained a section called <browserCaps>. This section contained a series of XML entries that defined the configurations for various browsers based on a regular expression. For ASP.NET version 2.0, a new .BROWSER file defines the parameters of a particular browser using XML entries. You add information on a new browser by adding a new .BROWSER file to the folder located at %SystemRoot%\Microsoft.NET\Framework\version\CONFIG\Browsers on your system.

Because an application is not reading a .config file every time it requires browser information, you can create a new .BROWSER file and run Aspnet_regbrowsers.exe to add the required changes to the assembly. This allows the server to access the new browser information immediately so you do not have to shut down any of your applications to pick up the information. An application can access browser capabilities through the Browser property of the current HttpRequest.

The following options are available when running aspnet_regbrowser.exe:

OPTION	DESCRIPTION
-?	Displays the Aspnet_regbbrowsers.exe Help text in the command window.
-i	Creates the runtime browser capabilities assembly and installs it in the global assembly cache.
-u	Uninstalls the runtime browser capabilities assembly from the global assembly cache.

The ASP.NET Compilation Tool - aspnet_compiler.exe

The ASP.NET Compilation tool can be used in two general ways: for in-place compilation and compilation for deployment, where a target output directory is specified.

Compiling an Application in Place

The ASP.NET Compilation tool can compile an application in place, that is, it mimics the behavior of making multiple requests to the application, thus causing regular compilation. Users of a pre-compiled site will not experience a delay caused by compiling the page on first request.

When you precompile a site in place, the following items apply:

- The site retains its files and directory structure.
- You must have compilers for all programming languages used by the site on the server.
- If any file fails compilation, the entire site fails compilation.

You can also recompile an application in place after adding new source files to it. The tool compiles only the new or changed files unless you include the **-c** option.

> **NOTE**
>
> Compilation of an application that contains a nested application does not compile the nested application. The nested application must be compiled separately.

Compiling an Application for Deployment

You compile an application for deployment (compilation to a target location) by specifying the targetDir parameter. The targetDir can be the final location for the Web application, or the compiled application can be further deployed. Using the **-u** option compiles the application in such a way that you can make changes to certain files in the compiled application without recompiling it. Aspnet_compiler.exe makes a distinction between static and dynamic file types, and handles them differently when creating the resulting application.

- Static file types are those that do not have an associated compiler or build provider, such as files whose named have extensions such as .css, .gif, .htm, .html, .jpg, .js and so on. These files are simply copied to the target location, with their relative places in the directory structure preserved.
- Dynamic file types are those that have an associated compiler or build provider, including files with ASP.NET-specific file name extensions such as .asax, .ascx, .ashx, .aspx, .browser, .master, and so on. The ASP.NET Compilation tool generates assemblies from these files. If the **-u** option is omitted, the tool also creates files with the file name extension .COMPILED that map the original source files to their assembly. To ensure that the directory structure of the application source is preserved, the tool generates placeholder files in the corresponding locations in the target application.

You must use the **-u** option to indicate that the content of the compiled application can be modified. Otherwise, subsequent modifications are ignored or cause run-time errors.

The following table describes how the ASP.NET Compilation tool handles different file types when the **-u** option is included.

FILE TYPE	COMPILER ACTION
.ascx, .aspx, .master	These files are split into markup and source code, which includes both code-behind files and any code that is enclosed in <script runat="server"> elements. Source code is compiled into assemblies, with names that are derived from a hashing algorithm, and the assemblies are placed in the Bin directory. Any inline code, that is, code enclosed between the **<%** and **%>** brackets, is included with markup and not compiled. New files with the same name as the source files are created to contain the markup and placed in the corresponding output directories.
.ashx, .asmx	These files are not compiled and are moved to the output directories as is and not compiled. If you wish to have the handler code compiled, place the code into source code files in the App_Code directory.
.cs, .vb, .jsl, .cpp (not including code-behind files for the file types listed earlier)	These files are compiled and included as a resource in assemblies that reference them. Source files are not copied to the output directory. If a code file is not referenced, it is not compiled.
Custom file types	These files are not compiled. These files are copied to the corresponding output directories.

FILE TYPE	COMPILER ACTION
Source code files in the App_Code subdirectory	These files are compiled into assemblies and placed in the Bin directory.
.resx and .resource files in the App_GlobalResources subdirectory	These files are compiled into assemblies and placed in the Bin directory. No App_GlobalResources subdirectory is created under the main output directory, and no .resx or .resources files located in the source directory are copied to the output directories.
.resx and .resource files in the App_LocalResources subdirectory	These files are not compiled and are copied to the corresponding output directories.
.skin files in the App_Themes subdirectory	The .skin files and static theme files are not compiled and are copied to the corresponding output directories.
.browser Web.config Static file types Assemblies already present in the Bin directory	These files are copied as is to the output directories.

The following table describes how the ASP.NET Compilation tool handles different file types when the **-u** option is omitted.

FILE TYPE	COMPILER ACTION
.aspx, .asmx, .ashx, .master	These files are split into markup and source code, which includes both code-behind files and any code that is enclosed in <script runat="server"> elements. Source code is compiled into assemblies, with names that are derived from a hashing algorithm. The resulting assemblies are placed in the Bin directory. Any inline code, that is, code enclosed between the **<%** and **%>** brackets, is included with markup and not compiled. The compiler creates new files to contain the markup with the same name as the source files. These resulting files are placed in the Bin directory. The compiler also creates files with the same name as the source files but with the extension .COMPILED that contain mapping information. The .COMPILED files are placed in the output directories corresponding to the original location of the source files.
.ascx	These files are split into markup and source code. Source code is compiled into assemblies and placed in the Bin directory, with names that are derived from a hashing algorithm. No markup files are generated.
.cs, .vb, .jsl, .cpp (not including code-behind files for the file types listed earlier)	Source code that is referenced by the assemblies generated from .ascx, .ashx, or .aspx files is compiled into assemblies and placed in the Bin directory. No source files are copied.
Custom file types	These files are compiled like dynamic files. Depending on the type of file they are based on, the compiler can place mapping files in the output directories.
Files in the App_Code subdirectory	Source code files in this subdirectory are compiled into assemblies and placed in the Bin directory.

FILE TYPE	COMPILER ACTION
Files in the App_GlobalResources subdirectory	These files are compiled into assemblies and placed in the Bin directory. No App_GlobalResources subdirectory is created under the main output directory. If the configuration file specifies appliesTo="All", .resx and .resources files are copied to the output directories. They are not copied if they are referenced by a BuildProvider.
.resx and .resource files in the App_LocalResources subdirectory	These files are compiled into assemblies with unique names and placed in the Bin directory. No .resx or .resource files are copied to the output directories.
.skin files in the App_Themes subdirectory	Themes are compiled into assemblies and placed in the Bin directory. Stub files are created for .skin files and placed in the corresponding output directory. Static files (such as .css) are copied to the output directories.
.browser Web.config Static file types Assemblies already present in the Bin directory	These files are copied as is to the output directory.

Fixed Assembly Names

Some scenarios, such as deploying a Web application using the MSI Windows Installer, require the use of consistent file names and contents, as well as consistent directory structures to identify assemblies or configuration settings for updates. In those cases, you can use the **-fixednames** option to specify that the ASP.NET Compilation tool should compile an assembly for each source file instead of using the where multiple pages are compiled into assemblies. This can lead to a large number of assemblies, so if you are concerned with scalability you should use this option with caution.

Strong-Name Compilation

The **-aptca**, **-delaysign**, **-keycontainer** and **-keyfile** options are provided so that you can use Aspnet_compiler.exe to create strongly named assemblies without using the Strong Name Tool (Sn.exe) separately. These options correspond, respectively, to **AllowPartiallyTrustedCallersAttribute**, **AssemblyDelaySignAttribute**, **AssemblyKeyNameAttribute**, and **AssemblyKeyFileAttribute**.

Discussion of these attributes is outside of the scope of this course.

Labs

Each of the following labs builds on the previous labs. You will need to do them in order.

Lab 1: Using the Configuration API

1. Create a new Web site called *mod9lab*.
2. Add a new Web Configuration File to the site.
3. Add the following to the web.config file:

```
<authorization>
    <deny users="?"/>
</authorization>

<identity impersonate="true"/>
```

This will ensure that you have permission to save changes to the web.config file.

1. Add a new Label control to Default.aspx and change the ID to **lblDebugStatus**.

2. Add a new Button control to Default.aspx.
3. Change the Button control's ID to **btnToggleDebug** and the Text to **Toggle Debug Status**.
4. Open the Code View for the code-behind file of Default.aspx and add a **using** statement for **System.Web.Configuration** as follows:

```
using System.Web.Configuration;
```

1. Add two private variables to the class and a Page_Init method as shown below:

```
public partial class _Default : System.Web.UI.Page {
    private bool _debugStatus;
    private CompilationSection compilation;
    private Configuration config;
    protected void Page_Init(object sender, EventArgs e) {
        config = WebConfigurationManager.OpenWebConfiguration("/mod9lab");
        compilation =
            (CompilationSection)config.GetSection("system.web/compilation");
        _debugStatus = compilation.Debug;
    }
}
```

1. Add the following code to Page_Load:

```
lblDebugStatus.Text = "Debug set to: " + _debugStatus.ToString();
```

1. Save and browse default.aspx. Notice that the Label control displays the current debug status.
2. Double-click on the Button control in the designer and add the following code to the Click event for the Button control:

```
compilation.Debug = !_debugStatus;
config.Save();
lblDebugStatus.Text = "Debug set to: " + compilation.Debug.ToString();
```

1. Save and browse default.aspx and click the button.
2. Open the web.config file after each button click and observe the **debug** attribute in the <compilation> section.

Lab 2: Logging Application Restarts

In this lab, you will create code that will allow you to toggle the logging of application shutdowns, startups, and recompilations in the Event Viewer.

1. Add a DropDownList to default.aspx and change the ID to ddlLogAppEvents.
2. Set the **AutoPostBack** property for the DropDownList to **true**.
3. Add three items to the Items collection for the DropDownList. Make the **Text** for the first item *Select Value* and the value -1. Make the **Text** and **Value** of the second item **True** and the **Text** and **Value** of the third item **False**.
4. Add a new Label to default.aspx. Change the ID to **lblLogAppEvents**.
5. Open the code-behind view for default.aspx and add a new declaration for a variable of type HealthMonitoringSection as shown below:

```
public partial class _Default : System.Web.UI.Page {
    private bool _debugStatus;
    private CompilationSection compilation;
    private Configuration config;

    // new variable below
    private HealthMonitoringSection health;
}
```

1. Add the following code to the existing code in Page_Init:

```
health = (HealthMonitoringSection)config.GetSection("system.web/healthMonitoring");
```

1. Double-click on the DropDownList and add the following code to the SelectedIndexChanged event:

```
if (ddlLogAppEvents.SelectedValue != "-1") {
    if (Convert.ToBoolean(ddlLogAppEvents.SelectedValue)) {
        RuleSettings appRules = new
        RuleSettings("AppRestartEvents",
        "Application Lifetime Events",
        "EventLogProvider");
        health.Rules.Add(appRules);
        config.Save();
    } else {
        health.Rules.Remove("AppRestartEvents");
        config.Save();
    }
}
```

1. Browse default.aspx.
2. Set the dropdown to **False**.
3. Clear the Application log in the Event Viewer.
4. Click the button to change the Debug attribute for the application.
5. Refresh the Application log in the Event Viewer.
   a. Were any events logged?
   b. Why or why not?
6. Set the dropdown to **True**.
7. Click the button to toggle the Debug attribute for the application.
8. Refresh the Application login the Event Viewer.
   a. Were any events logged?
   b. What was the reason for the app shutdown?
9. Experiment with turning on and off logging and look at the changes made to the web.config file.

More Information:

ASP.NET 2.0's Provider model allows you to create your own providers for not only application instrumentation, but for many other uses as well such as Membership, Profiles, etc. For detailed information on writing a custom provider to log application events to a text file, visit this link.

Profiles, Themes, and Web Parts

4/10/2020 • 42 minutes to read • Edit Online

by Microsoft

> There are major changes in configuration and instrumentation in ASP.NET 2.0. The new ASP.NET configuration API allows for configuration changes to be made programmatically. In addition, many new configuration settings exist allow for new configurations and instrumentation.

ASP.NET 2.0 represents a substantial improvement in the area of personalized Web sites. In addition to the membership features we've already covered, ASP.NET profiles, themes, and Web parts significantly enhance personalization in Web sites.

ASP.NET Profiles

ASP.NET profiles are similar to sessions. The difference is that a profile is persistent whereas a session is lost when the browser is closed. Another big difference between sessions and profiles is that profiles are strongly typed, therefore providing you with IntelliSense during the development process.

A profile is defined in either the machines configuration file or the web.config file for the application. (You cannot define a profile in a sub-folders web.config file.) The code below defines a profile to store the Web site visitors first and last name.

```
<profile>
    <properties>
        <add name="FirstName" />
        <add name="LastName" />
    </properties>
</profile>
```

The default data type for a profile property is System.String. In the above example, no data type was specified. Therefore the FirstName and LastName properties are both of type String. As previously mentioned, profile properties are strongly typed. The code below adds a new property for age that is of type Int32.

```
<profile>
    <properties>
        <add name="FirstName" />
        <add name="LastName" />
        <add name="Age" type="Int32"/>
    </properties>
</profile>
```

Profiles are generally used with ASP.NET Forms authentication. When used in combination with Forms authentication, each user has a separate profile associated with their user ID. However, it is also possible to allow the use of profiles in an anonymous application using the <anonymousIdentification> element in the configuration file along with the **allowAnonymous** attribute as shown below:

```
<anonymousIdentification enabled="true" />
<profile>
    <properties>
        <add name="FirstName" allowAnonymous="true" />
        <add name="LastName" allowAnonymous="true" />
    </properties>
</profile>
```

When an anonymous user browses the site, ASP.NET creates an instance of **ProfileCommon** for the user. This profile uses a unique ID stored in a cookie on the browser to identify the user as a unique visitor. In this way, you can store profile information for users who are browsing anonymously.

Profile Groups

It is possible to group properties of profiles. By grouping properties, it is possible to simulate multiple profiles for a specific application.

The following configuration configures a FirstName and LastName property for two groups; Buyers and Prospects.

```
<profile>
    <properties>
        <group name="Buyers">
            <add name="FirstName" />
            <add name="Lastname" />
            <add name="NumberOfPurchases" type="Int32" />
        </group>
        <group name="Prospects">
            <add name="FirstName" />
            <add name="Lastname" />
        </group>
    </properties>
</profile>
```

It is then possible to set properties on a particular group as follows:

```
Profile.Buyers.NumberOfPurchases += 1;
```

Storing Complex Objects

So far, the examples we've covered have stored simple data types in a profile. It is also possible to store complex data types in a profile by specifying the method of serialization using the **serializeAs** attribute as follows:

```
<add name="PurchaseInvoice"
     type="PurchaseInvoice"
     serializeAs="Binary"
/>
```

In this case, the type is PurchaseInvoice. The PurchaseInvoice class needs to be marked as serializable and can contain any number of properties. For example, if PurchaseInvoice has a property called **NumItemsPurchased**, you can refer to that property in code as follows:

```
Profile.PurchaseInvoice.NumItemsPurchased
```

Profile Inheritance

It is possible to create a profile for use in multiple applications. By creating a profile class that derives from ProfileBase, you can reuse a profile in several applications by using the **inherits** attribute as shown below:

```
<profile inherits="PurchasingProfile" />
```

In this case, the class **PurchasingProfile** would look like so:

```
using System;
using System.Web.Profile;
public class PurchasingProfile : ProfileBase {
    private string _ProductName;
    private Int32 _ProductID;
    public string ProductName {
        get { return _ProductName; }
        set { _ProductName = value; }
    }
    public Int32 ProductID {
        get { return _ProductID; }
        set { _ProductID = value; }
    }
}
```

Profile Providers

ASP.NET profiles use the provider model. The default provider stores the information in a SQL Server Express database in the App_Data folder of the Web application using the SqlProfileProvider provider. If the database doesn't exist, ASP.NET will automatically create it when the profile attempts to store information.

In some cases, however, you may want to develop your own profile provider. The ASP.NET profile feature enables you to easily use different providers.

You create a custom profile provider when:

- You need to store profile information in a data source, such as in a FoxPro database or in an Oracle database, that is not supported by the profile providers included with the .NET Framework.
- You need to manage profile information using a database schema that is different from the database schema used by the providers included with the .NET Framework. A common example is that you want to integrate profile information with user data in an existing SQL Server database.

Required Classes

To implement a profile provider, you create a class that inherits the System.Web.Profile.ProfileProvider abstract class. The **ProfileProvider** abstract class in turn inherits the System.Configuration.SettingsProvider abstract class, which inherits the System.Configuration.Provider.ProviderBase abstract class. Because of this inheritance chain, in addition to the required members of the **ProfileProvider** class, you must implement the required members of the **SettingsProvider** and **ProviderBase** classes.

The following tables describe the properties and methods that you must implement from the **ProviderBase**, **SettingsProvider**, and **ProfileProvider** abstract classes.

ProviderBase Members

MEMBER	DESCRIPTION

MEMBER	DESCRIPTION
Initialize method	Takes as input the name of the provider instance and a NameValueCollection of configuration settings. Used to set options and property values for the provider instance, including implementation-specific values and options specified in the machine configuration or Web.config file.

SettingsProvider Members

MEMBER	DESCRIPTION
ApplicationName property	The application name that is stored with each profile. The profile provider uses the application name to store profile information separately for each application. This enables multiple ASP.NET applications to use the same data source without a conflict if the same user name is created in different applications. Alternatively, multiple ASP.NET applications can share a profile data source by specifying the same application name.
GetPropertyValues method	Takes as input a SettingsContext and a SettingsPropertyCollection object. The **SettingsContext** provides information about the user. You can use the information as a primary key to retrieve profile property information for the user. Use the **SettingsContext** object to get the user name and whether the user is authenticated or anonymous. The **SettingsPropertyCollection** contains a collection of SettingsProperty objects. Each **SettingsProperty** object provides the name and type of the property as well as additional information such as the default value for the property and whether the property is read-only. The **GetPropertyValues** method populates a SettingsPropertyValueCollection with SettingsPropertyValue objects based on the **SettingsProperty** objects provided as input. The values from the data source for the specified user are assigned to the PropertyValue properties for each **SettingsPropertyValue** object and the entire collection is returned. Calling the method also updates the LastActivityDate value for the specified user profile to the current date and time.
SetPropertyValues method	Takes as input a **SettingsContext** and a **SettingsPropertyValueCollection** object. The **SettingsContext** provides information about the user. You can use the information as a primary key to retrieve profile property information for the user. Use the **SettingsContext** object to get the user name and whether the user is authenticated or anonymous. The **SettingsPropertyValueCollection** contains a collection of **SettingsPropertyValue** objects. Each **SettingsPropertyValue** object provides the name, type, and value of the property as well as additional information such as the default value for the property and whether the property is read-only. The **SetPropertyValues** method updates the profile property values in the data source for the specified user. Calling the method also updates the **LastActivityDate** and LastUpdatedDate values for the specified user profile to the current date and time.

ProfileProvider Members

MEMBER	DESCRIPTION
DeleteProfiles method	Takes as input a string array of user names and deletes from the data source all profile information and property values for the specified names where the application name matches the **ApplicationName** property value. If your data source supports transactions, it is recommended that you include all delete operations in a transaction and that you roll back the transaction and throw an exception if any delete operation fails.
DeleteProfiles method	Takes as input a collection of ProfileInfo objects and deletes from the data source all profile information and property values for each profile where the application name matches the **ApplicationName** property value. If your data source supports transactions, it is recommended that you include all delete operations in a transaction and roll back the transaction and throw an exception if any delete operation fails.
DeleteInactiveProfiles method	Takes as input a ProfileAuthenticationOption value and a DateTime object and deletes from the data source all profile information and property values where the last activity date is less than or equal to the specified date and time and where the application name matches the **ApplicationName** property value. The **ProfileAuthenticationOption** parameter specifies whether only anonymous profiles, only authenticated profiles, or all profiles are to be deleted. If your data source supports transactions, it is recommended that you include all delete operations in a transaction and roll back the transaction and throw an exception if any delete operation fails.
GetAllProfiles method	Takes as input a **ProfileAuthenticationOption** value, an integer that specifies the page index, an integer that specifies the page size, and a reference to an integer that will be set to the total count of profiles. Returns a ProfileInfoCollection that contains **ProfileInfo** objects for all profiles in the data source where the application name matches the **ApplicationName** property value. The **ProfileAuthenticationOption** parameter specifies whether only anonymous profiles, only authenticated profiles, or all profiles are to be returned. The results returned by the **GetAllProfiles** method are constrained by the page index and page size values. The page size value specifies the maximum number of **ProfileInfo** objects to return in the **ProfileInfoCollection**. The page index value specifies which page of results to return, where 1 identifies the first page. The parameter for total records is an out parameter (you can use **ByRef** in Visual Basic) that is set to the total number of profiles. For example, if the data store contains 13 profiles for the application and the page index value is 2 with a page size of 5, the **ProfileInfoCollection** returned contains the sixth through the tenth profiles. The total records value is set to 13 when the method returns.

MEMBER	DESCRIPTION
GetAllInactiveProfiles method	Takes as input a **ProfileAuthenticationOption** value, a **DateTime** object, an integer that specifies the page index, an integer that specifies the page size, and a reference to an integer that will be set to the total count of profiles. Returns a **ProfileInfoCollection** that contains **ProfileInfo** objects for all profiles in the data source where the last activity date is less than or equal to the specified **DateTime** and where the application name matches the **ApplicationName** property value. The **ProfileAuthenticationOption** parameter specifies whether only anonymous profiles, only authenticated profiles, or all profiles are to be returned. The results returned by the **GetAllInactiveProfiles** method are constrained by the page index and page size values. The page size value specifies the maximum number of **ProfileInfo** objects to return in the **ProfileInfoCollection**. The page index value specifies which page of results to return, where 1 identifies the first page. The parameter for total records is an out parameter (you can use **ByRef** in Visual Basic) that is set to the total number of profiles. For example, if the data store contains 13 profiles for the application and the page index value is 2 with a page size of 5, the **ProfileInfoCollection** returned contains the sixth through the tenth profiles. The total records value is set to 13 when the method returns.
FindProfilesByUserName method	Takes as input a **ProfileAuthenticationOption** value, a string containing a user name, an integer that specifies the page index, an integer that specifies the page size, and a reference to an integer that will be set to the total count of profiles. Returns a **ProfileInfoCollection** that contains **ProfileInfo** objects for all profiles in the data source where the user name matches the specified user name and where the application name matches the **ApplicationName** property value. The **ProfileAuthenticationOption** parameter specifies whether only anonymous profiles, only authenticated profiles, or all profiles are to be returned. If your data source supports additional search capabilities, such as wildcard characters, you can provide more extensive search capabilities for user names. The results returned by the **FindProfilesByUserName** method are constrained by the page index and page size values. The page size value specifies the maximum number of **ProfileInfo** objects to return in the **ProfileInfoCollection**. The page index value specifies which page of results to return, where 1 identifies the first page. The parameter for total records is an out parameter (you can use **ByRef** in Visual Basic) that is set to the total number of profiles. For example, if the data store contains 13 profiles for the application and the page index value is 2 with a page size of 5, the **ProfileInfoCollection** returned contains the sixth through the tenth profiles. The total records value is set to 13 when the method returns.

MEMBER	DESCRIPTION
FindInactiveProfilesByUserName method	Takes as input a **ProfileAuthenticationOption** value, a string containing a user name, a **DateTime** object, an integer that specifies the page index, an integer that specifies the page size, and a reference to an integer that will be set to the total count of profiles. Returns a **ProfileInfoCollection** that contains **ProfileInfo** objects for all profiles in the data source where the user name matches the specified user name, where the last activity date is less than or equal to the specified **DateTime**, and where the application name matches the **ApplicationName** property value. The **ProfileAuthenticationOption** parameter specifies whether only anonymous profiles, only authenticated profiles, or all profiles are to be returned. If your data source supports additional search capabilities, such as wildcard characters, you can provide more extensive search capabilities for user names. The results returned by the **FindInactiveProfilesByUserName** method are constrained by the page index and page size values. The page size value specifies the maximum number of **ProfileInfo** objects to return in the **ProfileInfoCollection**. The page index value specifies which page of results to return, where 1 identifies the first page. The parameter for total records is an out parameter (you can use **ByRef** in Visual Basic) that is set to the total number of profiles. For example, if the data store contains 13 profiles for the application and the page index value is 2 with a page size of 5, the **ProfileInfoCollection** returned contains the sixth through the tenth profiles. The total records value is set to 13 when the method returns.
GetNumberOfInActiveProfiles method	Takes as input a **ProfileAuthenticationOption** value and a **DateTime** object and returns a count of all profiles in the data source where the last activity date is less than or equal to the specified **DateTime** and where the application name matches the **ApplicationName** property value. The **ProfileAuthenticationOption** parameter specifies whether only anonymous profiles, only authenticated profiles, or all profiles are to be counted.

ApplicationName

Because profile providers store profile information separately for each application, you must ensure that your data schema includes the application name and that queries and updates also include the application name. For example, the following command is used to retrieve a property value from a database based on the user name and whether the profile is anonymous, and ensures that the **ApplicationName** value is included in the query.

```
SELECT Property
FROM PropertyTable
WHERE Username = 'user1'
AND IsAnonymous = False
AND ApplicationName = 'MyApplication'
```

ASP.NET Themes

What are ASP.NET 2.0 Themes?

One of the most important aspects of a Web application is a consistent look and feel across the site. ASP.NET 1.x developers usually use Cascading Style Sheets (CSS) to implement a consistent look and feel. ASP.NET 2.0 themes

significantly improve upon CSS because they give the ASP.NET developer the ability to define the appearance of ASP.NET server controls as well as HTML elements. ASP.NET themes can be applied to individual controls, a specific Web page, or an entire Web application. Themes use a combination of CSS files, an optional skin file, and an optional Images directory if images are needed. The skin file controls the visual appearance of ASP.NET server controls.

Where are Themes Stored?

The location where themes are stored differs based upon their scope. Themes that can be applied to any application are stored in the following folder:

`C:\WINDOWS\Microsoft.NET\Framework\v2.x.xxxxx\ASP.NETClientFiles\Themes\<Theme_Name>`

A theme that is specific to a particular application is stored in an `App\_Themes\<Theme\_Name>` directory in the root of the Web site.

> **NOTE**
> A skin file should only modify server control properties that affect appearance.

A global theme is a theme that can be applied to any application or Web site running on the Web server. These themes are stored by default in the ASP.NETClientfiles\Themes directory that is inside of the v2.x.xxxxx directory. Alternatively, you can move the theme files into the aspnet_client/system_web/[version]/Themes/[theme_name] folder in the root of your Web site.

Application-specific themes can only be applied to the application in which the files reside. These files are stored in the `App\_Themes/<theme\_name>` directory in the root of the Web site.

The Components of a Theme

A theme is made up of one or more CSS files, an optional skin file, and an optional Images folder. The CSS files can be any name you wish (i.e. default.css or theme.css, etc.) and must be in the root of the themes folder. The CSS files are used to define ordinary CSS classes and attributes for specific selectors. To apply one of the CSS classes to a page element, the **CSSClass** property is used.

The skin file is an XML file that contains property definitions for ASP.NET server controls. The code listed below is an example skin file.

```
<asp:TextBox runat="server"
    BackColor="#FFC080"
    BorderColor="Black"
    BorderStyle="Solid"
    BorderWidth="1px"
    Font-Names="Tahoma, Verdana, Arial"
    Font-Size="Smaller" />

<asp:Button runat="server"
    BackColor="#C04000"
    BorderColor="Maroon"
    BorderStyle="Solid"
    BorderWidth="2px"
    Font-Names="Tahoma,Verdana,Arial"
    Font-Size="Smaller"
    ForeColor="#FFFFC0" />
```

Figure 1 below shows a small ASP.NET page browsed without a theme applied. **Figure 2** shows the same file with a theme applied. The background color and text color are configured via a CSS file. The appearance of the

button and textbox are configured using the skin file listed above.

Figure 1: No Theme

Figure 2: Theme Applied

The skin file listed above defines a default skin for all TextBox controls and Button controls. That means that every TextBox control and Button control inserted on a page will take on this appearance. You can also define a skin that can be applied to specific instances of these controls using the **SkinID** property of the control.

The code below defines a skin for a Button control. Only Button controls with a **SkinID** property of **goButton** will take on the appearance of the skin.

```
<asp:Button runat="server"
    BackColor="#C04000"
    BorderColor="Maroon"
    BorderStyle="Solid"
    BorderWidth="2px"
    Font-Names="Tahoma,Verdana,Arial"
    Font-Size="Smaller"
    ForeColor="#FFFFC0"
    Text=go
    SkinID=goButton
    Width="95px" />
```

You can only have one default skin per server control type. If you require additional skins, you should use the SkinID property.

Applying Themes to Pages

A theme can be applied using any one of the following methods:

- In the <pages> element of the web.config file
- In the @Page directive of a page
- Programmatically

Applying a Theme in the Configuration File

To apply a theme in the applications configuration file, use the following syntax:

```
<system.web>
    <pages theme="CoolTheme" />
    ...
</system.web>
```

The theme name specified here must match the name of the themes folder. This folder can exist either in any one of the locations mentioned earlier in this course. If you attempt to apply a theme that doesn't exist, a configuration error will occur.

Applying a Theme in the Page Directive

You can also apply a theme in the @ Page directive. This method allows you to use a theme for a specific page.

To apply a theme in the @Page directive, use the following syntax:

```
<%@ Page Language="C#" Theme=CoolTheme CodeFile="Default.aspx.cs" ... %>
```

Once again, the theme specified here must match the theme folder as mentioned previously. If you attempt to apply a theme that doesn't exist, a build failure will occur. Visual Studio will also highlight the attribute and notify you that no such theme exists.

Applying a Theme Programmatically

To apply a theme programmatically, you must specify the **Theme** property for the page in the **Page_PreInit** method.

To apply a theme programmatically, use the following syntax:

```
Page.Theme = CoolTheme;
```

It is necessary to apply the theme in the PreInit method due to the page lifecycle. If you apply it after that point, the pages theme will have already been applied by the runtime and a change at that point is too late in the lifecycle. If you apply a theme that doesn't exist, an **HttpException** occurs. When a theme is applied programmatically, a build warning will occur if any server controls have a SkinID property specified. This warning is intended to inform you that no theme is declaratively applied and it can be ignored.

Exercise 1 : Applying a Theme

In this exercise, you will apply an ASP.NET theme to a Web site.

> **IMPORTANT**
> If you are using Microsoft Word to enter information into a skin file, make sure that you are not replacing regular quotes with smart quotes. Smart quotes will cause problems with skin files.

1. Create a new ASP.NET Web site.
2. Right-click on the project in Solution Explorer and choose Add New Item.
3. Choose Web Configuration File from the list of files and click Add.
4. Right-click on the project in Solution Explorer and choose Add New Item.
5. Choose Skin File and click Add.

6. Click Yes when asked if you'd like to place the file inside of the App_Themes folder.
7. Right-click on the SkinFile folder inside of the App_Themes folder in Solution Explorer and choose Add New Item.
8. Choose Style Sheet from the list of files and click Add. You now have all of the files necessary to implement your new theme. However, Visual Studio has named your themes folder SkinFile. Right-click on that folder and change the name to CoolTheme.
9. Open the SkinFile.skin file and add the following code the end of the file:

```
<asp:TextBox runat="server"
    BackColor="#FFC080"
    BorderColor="Black"
    BorderStyle="Solid"
    BorderWidth="1px"
    Font-Names="Tahoma, Verdana, Arial"
    Font-Size="Smaller"
/>

<asp:Button runat="server"
    BackColor="#C04000"
    BorderColor="Maroon"
    BorderStyle="Solid"
    BorderWidth="2px"
    Font-Names="Tahoma,Verdana,Arial"
    Font-Size="Smaller"
    ForeColor="#FFFFC0"
/>

<asp:Button runat="server"
    BackColor="#C04000"
    BorderColor="Maroon"
    BorderStyle="Solid"
    BorderWidth="2px"
    Font-Names="Tahoma,Verdana,Arial"
    Font-Size="Smaller"
    ForeColor="#FFFFC0"
    Text="go"
    SkinID="goButton"
    Width="95px"
/>
```

10. Save the SkinFile.skin file.
11. Open the StyleSheet.css.
12. Replace all of the text in it with the following:

```
body {
    background-color: #FFDEAD;
}
```

13. Save the StyleSheet.css file.
14. Open the Default.aspx page.
15. Add a TextBox control and a Button control.
16. Save the page. Now browse the Default.aspx page. It should display as a normal Web form.
17. Open the web.config file.

18. Add the following directly underneath the opening `<system.web>` tag:

```
<pages theme="CoolTheme" />
```

19. Save the web.config file. Now browse the Default.aspx page. It should display with the theme applied.
20. If it's not already open, open the Default.aspx page in Visual Studio.
21. Select the Button.
22. Change the **SkinID** property to goButton. Notice that Visual Studio provides a dropdown with valid SkinID values for a Button control.
23. Save the page. Now preview the page in your browser again. The Button should now say "go" and should be wider in appearance.

Using the **SkinID** property, you can easily configure different skins for different instances of a particular type of server control.

The StyleSheetTheme Property

So far, we've talked only about applying themes using the Theme property. When using the Theme property, the skin file will override any declarative settings for server controls. For example, in exercise 1, you specified a SkinID of "goButton" for the Button control and that changed the Button's text to "go". You may have noticed that the Text property of the Button in the designer was set to "Button", but the theme overrode that. The theme will always override any property settings in the designer.

If you'd like to be able to override the properties defined in the theme's skin file with properties specified in the designer, you can use the **StyleSheetTheme** property instead of the Theme property. The StyleSheetTheme property is the same as the Theme property except that it does not override all explicit property settings like the Theme property does.

To see this in action, open the web.config file from the project in exercise 1 and change the `<pages>` element to the following:

```
<pages styleSheetTheme="CoolTheme" />
```

Now browse the Default.aspx page and you'll see that the Button control has a Text property of "Button" again. That's because the explicit property setting in the designer is overriding the Text property set by the goButton SkinID.

Overriding Themes

A global theme can be overridden by applying a theme by the same name in the App_Themes folder of the application. However, the theme is not applied in a true override scenario. If the runtime encounters theme files in the App_Themes folder, it will apply the theme using those files and will ignore the global theme.

The StyleSheetTheme property is overridable and can be overridden in code as follows:

```
const String THEME_NAME = "CoolTheme";
public override string StyleSheetTheme {
    get { return THEME_NAME; }
    set { Page.StyleSheetTheme = THEME_NAME; }
}
```

Web Parts

ASP.NET Web Parts is an integrated set of controls for creating Web sites that enable end users to modify the content, appearance, and behavior of Web pages directly from a browser. The modifications can be applied to all users on the site or to individual users. When users modify pages and controls, the settings can be saved to retain a user's personal preferences across future browser sessions, a feature called personalization. These Web Parts capabilities mean that developers can empower end users to personalize a Web application dynamically, without developer or administrator intervention.

Using the Web Parts control set, you as a developer can enable end users to:

- Personalize page content. Users can add new Web Parts controls to a page, remove them, hide them, or minimize them like ordinary windows.
- Personalize page layout. Users can drag a Web Parts control to a different zone on a page, or change its appearance, properties, and behavior.
- Export and import controls. Users can import or export Web Parts control settings for use in other pages or sites, retaining the properties, appearance, and even the data in the controls. This reduces data entry and configuration demands on end users.
- Create connections. Users can establish connections between controls so that, for example, a chart control could display a graph for the data in a stock ticker control. Users could personalize not only the connection itself, but the appearance and details of how the chart control displays the data.
- Manage and personalize site-level settings. Authorized users can configure site-level settings, determine who can access a site or page, set role-based access to controls, and so on. For example, a user in an administrative role could set a Web Parts control to be shared by all users, and prevent users who are not administrators from personalizing the shared control.

You will typically work with Web Parts in one of three ways: creating pages that use Web Parts controls, creating individual Web Parts controls, or creating complete, personalizable Web applications, such as a portal.

Page Development

Page developers can use visual design tools such as Microsoft Visual Studio 2005 to create pages that use Web Parts. One advantage in using a tool such as Visual Studio is that the Web Parts control set provides features for drag-and-drop creation and configuration of Web Parts controls in a visual designer. For example, you can use the designer to drag a Web Parts zone, or a Web Parts editor control, onto the design surface, and then configure the control right in the designer using the UI provided by the Web Parts control set. This can speed development of Web Parts applications and reduce the amount of code you have to write.

Control Development

You can use any existing ASP.NET control as a Web Parts control, including standard Web server controls, custom server controls, and user controls. For maximum programmatic control of your environment, you can also create custom Web Parts controls that derive from the WebPart class. For individual Web Parts control development, you will typically either create a user control and use it as a Web Parts control, or develop a custom Web Parts control.

As an example of developing a custom Web Parts control, you could create a control to provide any of the features provided by other ASP.NET server controls that might be useful to package as a personalizable Web Parts control: calendars, lists, financial information, news, calculators, rich text controls for updating content, editable grids that connect to databases, charts that dynamically update their displays, or weather and travel information. If you provide a visual designer with your control, then any page developer using Visual Studio can simply drag your control into a Web Parts zone and configure it at design time without having to write additional code.

Personalization is the foundation of the Web Parts feature. It enables users to modify--or personalize--the layout, appearance, and behavior of Web Parts controls on a page. The personalized settings are long-lived: they are

persisted not just during the current browser session (as with view state), but also in long-term storage, so that a user's settings are saved for future browser sessions as well. Personalization is enabled by default for Web Parts pages.
